## *Abstract*

We analyze how trust affects the transmission of negative demand and supply shocks using a behavioural macroeconomic model. We define trust to have two dimensions: trust in the central bank's inflation target and trust in the future of economic activity. We find, first, that when large negative shocks occur the subsequent trajectories taken by output gap and inflation typically coalesce around a good and a bad trajectory. Second, these good and bad trajectories are correlated with movements in trust. In the bad trajectories trust collapses, in the good trajectories it is not affected. This feature is stronger when a negative supply shock occurs than in the case of a negative demand shock. Third, initial conditions (history) matters. Unfavorable initial conditions drive the economy into a bad trajectory, favorable initial conditions produce good trajectories. Fourth, we provide sensitivity analyses of our results with respect to the size of the shocks and the intensity of output stabilization. Fifth, we develop a case study comparing the supply shocks of the 1970s with the recent covid supply shock.

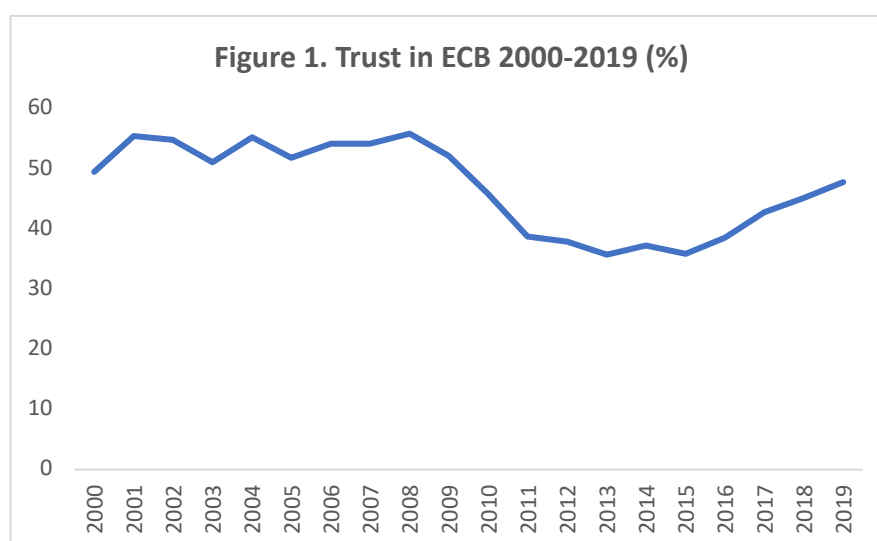

---

<sup>1</sup> We are grateful to Jean-Philippe Bouchaud, Geert Dhaene and Eddie Gerba for their very useful comments and suggestions. We also profited from many comments and useful suggestions made during seminars at the London School of Economics, the Collège de France, University of Munich, University College London, the University of Amsterdam, the University of Bamberg, Jaume University, the University of Strasbourg, the Danish National Bank and the Czech National Bank.

## 1. Introduction

The importance of trust in economic life is pervasive. Trust in the quality of institutions, trust in the executive and judiciary, trust in a stable environment governed by the rule of law, they all affect the behaviour of economic agents and makes them more willing to engage in contractual arrangements, to plan and to invest. There is now a large literature documenting how trust matters for economic development and growth<sup>2</sup>.

Trust also plays a role in standard macroeconomic models. These now typically incorporate a central bank that announces an inflation target. The credibility of this inflation target and reputation of the central bank usually play an important role in the effectiveness of monetary policies and in the transmission of shocks (Barro and Gordon (1983)). As a way of illustrating the importance of trust consider the Eurobarometer survey shown in Figure 1. According to this survey the European Central Bank (ECB) enjoyed a relatively high public trust record prior to 2008. This high level of trust was associated with a rate of inflation close to the 2% target rate (see Figure 2). As will be shown in this paper, trust in the central bank's ability to maintain price stability matters for the way monetary policies and exogenous shocks are transmitted into the economy. This is the first dimension of trust we will consider.

Source: Eurobarometer

Note: Trust is defined as the percentage of EU-citizens declaring that they have trust in the ECB

---

<sup>2</sup> The literature on how trust affects economic behaviour and ultimately economic growth and development is substantial. It is not the place here to present an exhaustive survey. Here are a few representative references: Arrow(1972), Putnam(1993) and (2000), Fukuyama(1995), Knack and Keefer(1997), La Porta, et al. (1997), Guiso, et al.(2000), Glaeser, et al. (2000), Acemoglu et al. (2003), Beugelsdijk, et al. (2004), Akçomak and ter Weel(2008), Dasgupta(2010), Tabellini(2010), Algan and Cahuc(2010) and (2013), Bjørnskov(2018)

Source: Eurostat

Trust has a second dimension related to confidence in the future. Trust here means a belief that future economic activity will be strong. Conversely, lack of trust means that there is pessimism about future economic activity. It has been found that since the global financial crisis and the deep economic recession that followed it (see Figure 2), public trust in the European Central Bank significantly declined in the Eurozone as shown in Figure 1. Note also from Figure 2 that the inflation rate during the same period became more variable despite its low level. This suggests that trust in the central bank can also be undermined when it is perceived to fail in maintaining macroeconomic stability (see more studies such as Wälti (2012), Ehrmann and Stracca (2013), Roth, et al. (2016)).

In this paper we wish to pursue the analysis of trust in macroeconomic modeling more systematically. We will use a behavioural macroeconomic model (see De Grauwe(2012, and De Grauwe and Ji(2019)) to analyze trust. This is a model which assumes that agents have cognitive limitations. They do not know the underlying structure of the model nor do they know the distribution of the shocks that affect the economy. It will be seen that in such models with imperfect information trust is of great importance to understand how shocks are transmitted and how monetary policies affect the economy.

The behavioural macroeconomic model we will use generates an endogenous dynamics of booms and busts in economic activity. This dynamics is driven by self-fulfilling movements of optimism and pessimism (animal spirits). The fundamental reason of the emergence of such a dynamics is the fact that individuals have cognitive limitations preventing them from having

rational expectations, i.e. preventing them from understanding the complexity of the underlying model. This lack of understanding provides the basis of a mechanism in which individuals find it rational to use simple rules of behaviour, check ex post how well these rules have worked and are willing to experiment with other rules when they observe that these work better. It also turns out that the shifting in the rules of behaviour at the individual level generates a collective process of herding based on the fact that successful rules will be copied by others. It is this collective process that is at the core of the waves of optimism and pessimism driving the business cycle movements and influencing the credibility of the central bank. It also follows that trust becomes an endogenous variable.

In this paper we will analyze how demand and supply shocks are propagated. We will focus on large shocks (to be defined appropriately). It will be shown that when the size of the shocks is large enough the transmission path after the shock will tend to coalesce around two possible trajectories, a good one and a bad one, as if there are two attractors around which the transmission dynamics is organized. It will be shown that the good trajectory coincides with a state of trust, while in the bad trajectory distrust prevails. This feature will also allow us to focus on the importance of initial conditions in guiding the economy towards the good or the bad trajectories. In other words we will show that history matters.

The rest of the paper is structured as follows. Section 2 presents the behavioural macroeconomic model. We will develop the essence of that model and put some more technical material in appendix. Section 3 presents the impulse responses of large demand and supply shocks and show how the trajectories taken by these impulse responses are associated with trust. This section also contains a Monte Carlo simulation aimed at checking the robustness of our results by allowing a wide selection of parameters. Section 4 analyzes the power of initial conditions in predicting the subsequent trajectories of output gap, inflation and interest rate. Section 5 performs a sensitivity analysis allowing us to trace the transition from small to large shocks. Section 6 discusses the power of output stabilization and how it affects trust in response to supply shocks. Section 7 provides for a short historical analysis of large shocks during the 1970s and during the pandemic. Section 8 concludes and provides policy implications.

## 2. The model

### 2.1 Basic equations

The basic behavioral macroeconomic model consists of an aggregate demand equation, an aggregate supply equation and a Taylor rule as described by De Grauwe (2011) and De Grauwe and Ji(2019). The aggregate demand and supply equations can be derived from expected utility maximization of consumers and expected profit maximization of firms (Hommes and Lustenhouwer(2019) and De Grauwe and Ji(2020)). In Appendix 1 we provide for such a microfoundation.

The aggregate demand equation obtained from this microfoundation can be expressed in the following way:

$$y_t = a_1 \tilde{E}_t y_{t+1} + (1 - a_1) y_{t-1} + a_2 (r_t - \tilde{E}_t \pi_{t+1}) + v_t \quad (1)$$

where  $y_t$  is the output gap in period  $t$ ,  $r_t$  is the nominal interest rate,  $\pi_t$  is the rate of inflation and two forward looking components,  $\tilde{E}_t \pi_{t+1}$  and  $\tilde{E}_t y_{t+1}$ . The tilde above  $E$  refers to the fact that expectations are not formed rationally. How exactly these expectations are formed will be specified subsequently.

The aggregate supply equation is represented in (2). This New Keynesian Philips curve includes a forward looking component,  $\tilde{E}_t \pi_{t+1}$ , and a lagged inflation variable. Inflation  $\pi_t$  is sensitive to the output gap  $y_t$ . The parameter  $b_2$  measures the extent to which inflation adjusts to changes in the output gap.

$$\pi_t = b_1 \tilde{E}_t \pi_{t+1} + (1 - b_1) \pi_{t-1} + b_2 y_t + \eta_t \quad (2)$$

The Taylor rule describes the central bank's behaviour in setting the interest rate. This behavior can be described as follows:

$$r_t = (1 - c_3)[c_1(\pi_t - \pi^*) + c_2 y_t] + c_3 r_{t-1} + u_t \quad (3)$$

where  $r_t$  is the interest rate in period  $t$ ,  $\pi_t$  is the inflation rate,  $\pi^*$  is the target rate of inflation and  $y_t$  is the output gap.

This Taylor rule tells us that the central bank increases (reduces) the interest rate when currently observed inflation exceeds (falls short of) the target and when the currently observed output gap is positive (negative). We assume that the central bank wants to smoothen interest rate changes (see Levin et al. (1999) and Woodford (1999, 2003)). This is shown by including a

lagged interest rate. When no smoothing occurs  $c_3 = 0$  we obtain the original Taylor rule. Note also that we set the natural rate of interest equal to zero.

We have also added error terms in each of the equations (1) to (3). These describe the nature of the different shocks that can hit the economy. There are demand shocks,  $v_t$ , supply shocks,  $\eta_t$  and interest rate shocks,  $u_t$ . It is assumed that these shocks are normally distributed with mean zero and a constant standard deviation.

## 2.2 Expectations formation

In this section we analyze how the forecast of output gap  $\tilde{E}_t y_{t+1}$  and inflation  $\tilde{E}_t \pi_{t+1}$  are formed in the model. The rational expectations hypothesis requires agents to understand the complexities of the underlying model and to know the frequency distributions of the shocks that will hit the economy. We take it that agents have cognitive limitations that prevent them from understanding and processing this kind of information. These cognitive limitations have been confirmed by laboratory experiments and survey data (see Branch, 2004; Pfajfar, D. and B. Zakelj, (2011 & 2014); Hommes, 2011).

### *Forecasting output gap*

We assume two types of rules agents follow to forecast the output gap. A first rule is called a “fundamentalist” one. Agents estimate the steady state value of the output gap (which is normalized at 0) and use this to forecast the future output gap. A second forecasting rule is a “naïve” extrapolative one. This is a rule that does not presuppose that agents know the steady state output gap. They are agnostic about it. Instead, they extrapolate the previous observed output gap into the future. There is ample evidence from laboratory experiments that support these assumptions that agents use simple heuristics to forecast output gap and inflation. See Pfajfar and Zakelj, (2011 & 2014), Kryvtsov and Petersen (2020) and also Assenza et al. (2014a) for a literature survey. The fundamentalist and extrapolator rules for output gap are specified as follows:

$$\tilde{E}_t^f y_{t+1} = 0 \quad (4)$$

$$\tilde{E}_t^e y_{t+1} = y_{t-1} \quad (5)$$

This kind of simple heuristic has often been used in the behavioral macroeconomics and finance literature where agents are assumed to use fundamentalist and chartist rules (see Brock and Hommes (1997), Branch and Evans (2006), De Grauwe and Grimaldi (2006), Brazier et al.

(2008)). It is probably the simplest possible assumption one can make about how agents who experience cognitive limitations, use rules that embody limited knowledge to guide their behavior. They only require agents to use information they understand, and do not require them to understand the whole picture. In De Grauwe (2012) more complex rules are used, e.g. it is assumed that agents do not know the steady state output gap with certainty and only have biased estimates of it. This is also the approach taken by Hommes and Lustenhouwer (2019). In De Grauwe(2012) we also allow a choice between more than two rules, and we assume more complex extrapolation rules.

The market forecast can be obtained as a weighted average of these two forecasts, i.e.

$$\tilde{E}_t y_{t+1} = \alpha_{f,t} \tilde{E}_t^f y_{t+1} + \alpha_{e,t} \tilde{E}_t^e y_{t+1} \quad (6)$$

$$\alpha_{f,t} + \alpha_{e,t} = 1 \quad (7)$$

where  $\alpha_{f,t}$  and  $\alpha_{e,t}$  are the probabilities that agents use the fundamentalist and the naïve rule respectively.

As indicated earlier, agents in our model are willing to learn, i.e. they continuously evaluate their forecast performance. We specify a switching mechanism of how agents adopt specific rule. As shown in Appendix 2, we follow the discrete choice theory (see Anderson, de Palma, and Thisse, (1992) and Brock & Hommes (1997)) to work out the probability of choosing a particular rule. We obtain:

$$\alpha_{f,t} = \frac{\exp(\gamma U_{f,t})}{\exp(\gamma U_{f,t}) + \exp(\gamma U_{e,t})} \quad (8)$$

$$\alpha_{e,t} = \frac{\exp(\gamma U_{e,t})}{\exp(\gamma U_{f,t}) + \exp(\gamma U_{e,t})} \quad (9)$$

where  $U_{f,t}$  and  $U_{e,t}$  the past forecast performance (utility) of using the fundamentalist and the naïve rules. The parameter  $\gamma$  measures the “intensity of choice”. It can also be interpreted as expressing a willingness to learn from past performance. When  $\gamma = 0$  this willingness is zero; it increases with the size of  $\gamma$ .

The forecast performance affects the probability of using a particular rule. For example, as shown in Equation (8), as the past forecast performance (utility) of the fundamentalist rule improves relative to that of the naïve rule, agents are more likely to select the fundamentalist rule for their forecasts of the output gap.

### ***Forecasting inflation***

Agents also forecast inflation. A similar simple heuristics is used as in the case of output gap forecasting, with one rule that could be called a fundamentalist rule and the other a extrapolative (naïve) rule. (See Brazier et al. (2008) for a similar setup). We assume an institutional set-up in which the central bank announces an explicit inflation target. The fundamentalist rule then is based on this announced inflation target, i.e. agents using this rule have confidence in the credibility of this rule and use it to forecast inflation. Agents who do not trust the announced inflation target use the naïve rule, which consists in extrapolating inflation from the past into the future. This allows us to define the first dimension as the fraction of agents that use the fundamentalist rule as their forecasting rule. They do this because they trust the central bank in keeping the inflation close to the announced target.

The fundamentalist rule will be called an “inflation targeting” rule. It consists in using the central bank’s inflation target to forecast future inflation, i.e.

$$\tilde{E}_t^f \pi_{t+1} = \pi^* \quad (10)$$

where the inflation target is  $\pi^*$ . The “naive” rule is defined by

$$\tilde{E}_t^e \pi_{t+1} = \pi_{t-1} \quad (11)$$

The market forecast is a weighted average of these two forecasts, i.e.

$$\tilde{E}_t \pi_{t+1} = \beta_{f,t} \tilde{E}_t^f \pi_{t+1} + \beta_{e,t} \tilde{E}_t^e \pi_{t+1} \quad (12)$$

$$\beta_{f,t} + \beta_{e,t} = 1 \quad (13)$$

Where  $\beta_{f,t}$  and  $\beta_{e,t}$  are the probabilities that agents use the fundamentalist and the extrapolative rule respectively. The same selection mechanism is used as in the case of output forecasting to determine the probabilities of agents trusting the inflation target and those who do not trust it and revert to extrapolation of past inflation. This inflation forecasting heuristics can be interpreted as a procedure of agents to find out how credible the central bank’s inflation targeting is. If this is very credible, using the announced inflation target will produce good forecasts and as a result, the probability,  $\beta_{f,t}$ , that agents will rely on the inflation target will be high. If on the other hand the inflation target does not produce good forecasts (compared to a simple extrapolation rule) the probability that agents will use it will be small. Using the switching mechanism similar to the one specified in equations (8) and (9), we can compute the probability of choosing a particular rule. More details can be found in Appendix 2.

$$\beta_{f,t} = \frac{\exp(\gamma U'_{f,t})}{\exp(\gamma U'_{f,t}) + \exp(\gamma U'_{e,t})} \quad (14)^3$$

$$\beta_{e,t} = \frac{\exp(\gamma U'_{e,t})}{\exp(\gamma U'_{f,t}) + \exp(\gamma U'_{e,t})} \quad (15)$$

The probability,  $\beta_{f,t}$ , that agents will rely on the inflation target to make inflation forecasts can also be interpreted as the fraction of agents who trust the central bank's inflation target.

### 2.3 Defining trust

The output and inflation expectation formation discussed in section 2.2 allows us to enlarge the definition of trust. We assume it has two dimensions. The first dimension is an institutional one. It is the trust in the central bank that has announced an inflation target. We will therefore use trust as a corollary of the credibility of the central bank. A central bank that has built a strong credibility of its inflation target is an institution that is trusted when it promises price stability. We measure the institutional trust by the fraction of agents,  $\beta_{f,t}$ , using the inflation target as their forecasting rule.

A second dimension is trust in the future. We will measure this by the degree of optimism about future economic activity. Trust here will mean a belief that future economic activity will be strong. Conversely, lack of trust will mean that there is pessimism about future economic activity. The forecasts made by extrapolators and fundamentalists play an important role. In order to highlight this role we define an index of market sentiments  $S_t$ , called "animal spirits" which will form the basis for our analysis of trust. This index can change between -1 and +1. It reflects how optimistic or pessimistic these forecasts are. It is obtained from the fraction of extrapolators ( $\alpha_{e,t}$ ) and fundamentalists ( $\alpha_{f,t}$ ) as follows:

$$S_t = \begin{cases} \alpha_{e,t} - \alpha_{f,t} & \text{if } y_{t-1} > 0 \\ -\alpha_{e,t} + \alpha_{f,t} & \text{if } y_{t-1} < 0 \end{cases} \quad (16)$$

This index can change between -1 and +1. There are two possibilities:

- When  $y_{t-1} > 0$ , extrapolators forecast a positive output gap. The fraction of agents who make such a positive forecasts is  $\alpha_{e,t}$ . Fundamentalists, however, then make a pessimistic forecast since they expect the positive output gap to decline towards the equilibrium value

---

<sup>3</sup> Note  $U'_{f,t} = -\sum_{k=0}^{\infty} \omega_k [\pi_{t-k-1} - \tilde{E}_{f,t-k-2} \pi_{t-k-1}]^2$  and  $U'_{e,t} = -\sum_{k=0}^{\infty} \omega_k [\pi_{t-k-1} - \tilde{E}_{e,t-k-2} \pi_{t-k-1}]^2$

of 0. The fraction of agents who make such a forecast is  $\alpha_{f,t}$ . We subtract this fraction of pessimistic forecasts from the fraction  $\alpha_{e,t}$  who make a positive forecast. When these two fractions are equal to each other (both are then 0.5) market sentiments (animal spirits) are neutral, i.e. optimists and pessimists cancel out and  $S_t = 0$ . When the fraction of optimists  $\alpha_{e,t}$  exceeds the fraction of pessimists  $\alpha_{f,t}$ ,  $S_t$  becomes positive. As we will see, the model allows for the possibility that  $\alpha_{e,t}$  moves to 1. In that case there are only optimists and  $S_t = 1$ .

- When  $y_{t-1} < 0$ , extrapolators forecast a negative output gap. The fraction of agents who make such a negative forecasts is  $\alpha_{e,t}$ . We give this fraction a negative sign. Fundamentalists, however, then make an optimistic forecast since they expect the negative output gap to increase towards the equilibrium value of 0. The fraction of agents who make such a forecast is  $\alpha_{f,t}$ . We give this fraction of optimistic forecasts a positive sign. When these two fractions are equal to each other (both are then 0.5) market sentiments (animal spirits) are neutral, i.e. optimists and pessimists cancel out and  $S_t = 0$ . When the fraction of pessimists  $\alpha_{e,t}$  exceeds the fraction of optimists  $\alpha_{f,t}$   $S_t$  becomes negative. The fraction of pessimists,  $\alpha_{e,t}$ , can move to 1. In that case there are only pessimists and  $S_t = -1$  and we conclude that trust about the future is at its lowest point. When  $S_t = 1$  trust about the future is at its highest.

## 2.4. Calibration

As our model has strong non-linear features we use numerical methods to analyze the dynamics created by the model. In order to do so, we have to calibrate the model, i.e. to select numerical values for the parameters of the model. In Table 2 we show these numerical values with the references from the literature. The model was calibrated in such a way that the time units can be considered to be quarters. The three shocks (demand shocks, supply shocks and interest rate shocks) are independently and identically distributed (i.i.d.) with standard deviations of 0.5%. These shocks produce standard deviations of the output gap and inflation that mimic the standard deviations found in the empirical data using quarterly observations for the US and the Eurozone. The way we did this is be described in more detail in De Grauwe and Ji(2020). It should also be mentioned that the parameter values in Table 1 ensure local stability of the steady state. Finally, to simplify our analysis, we remove the structural inertia components in the demand and the supply equations. Hence, we set  $a_1=1$  and  $b_1=1$ . It turns out that our results are not fundamentally affected by this assumption. Finally, we will perform a Monte Carlo

experiment varying the numerical values of different parameters to check the robustness of our results.

**Table 2: Parameter values of the calibrated model**

$a1 = 0.5$	coefficient of expected output in output equation (Smets and Wouters(2003))
$a2 = -0.2$	interest elasticity of output demand (McCallum and Nelson (1999)).
$b1 = 0.5$	coefficient of expected inflation in inflation equation (Smets and Wouters (2003))
$b2 = 0.05$	coefficient of output in inflation equation,
$\pi^* = 0$	inflation target level
$c1 = 1.5$	coefficient of inflation in Taylor equation (Blattner and Margaritov(2010))
$c2 = 0.5$	coefficient of output in Taylor equation assuming a dual Mandate Central Bank (Blattner and Margaritov(2010))
$c3 = 0.5$	interest smoothing parameter in Taylor equation (Blattner and Margaritov(2010))
$\gamma = 2$	intensity of choice parameter, see Kukacka, Jang and Sacht (2018)
$\sigma_v = 0.5$	standard deviation shocks output
$\sigma_\eta = 0.5$	standard deviation shocks inflation
$\sigma_u = 0.5$	standard deviation shocks Taylor
$\rho = 0.5$	memory parameter (see footnote 4)

### 3 The results of the model

In this section we present impulse responses of demand and supply shocks. One important feature of impulse responses in a (non-linear) behavioural model is that these responses are sensitive to initial conditions. Thus, the transmission of, say, a demand shock will be influenced by the values of output, inflation, interest rate and the expectations of these variables at the moment the shock occurs. This also means that the timing of the shock matters. The same shock at one point in time may be transmitted very differently from one that occurs at a different time, as will be made clear in this section.

The way we computed the impulse responses to a particular shock was the following. We first run a base simulation using a particular realization of all the stochastic variables (the error terms in the demand, supply and Taylor rule equations). We then rerun the model with exactly the same realizations of these stochastic variables except for the fact that at period  $t = 100$  a shock is introduced in the demand or in the supply equation. We then compute the differences between the output gap in the series with the shock and the series obtained in the base simulation. We also expressed these differences as ‘multipliers’, i.e. we divided them by the size of the shock. This yielded one particular impulse response for a given set of realizations of the stochastic variables. We repeated this 1000 times, each time with another realization of

the stochastic variables in the model. This then yielded 1000 different impulse responses to the same shock, but with different initial conditions of the endogenous variables of the model.

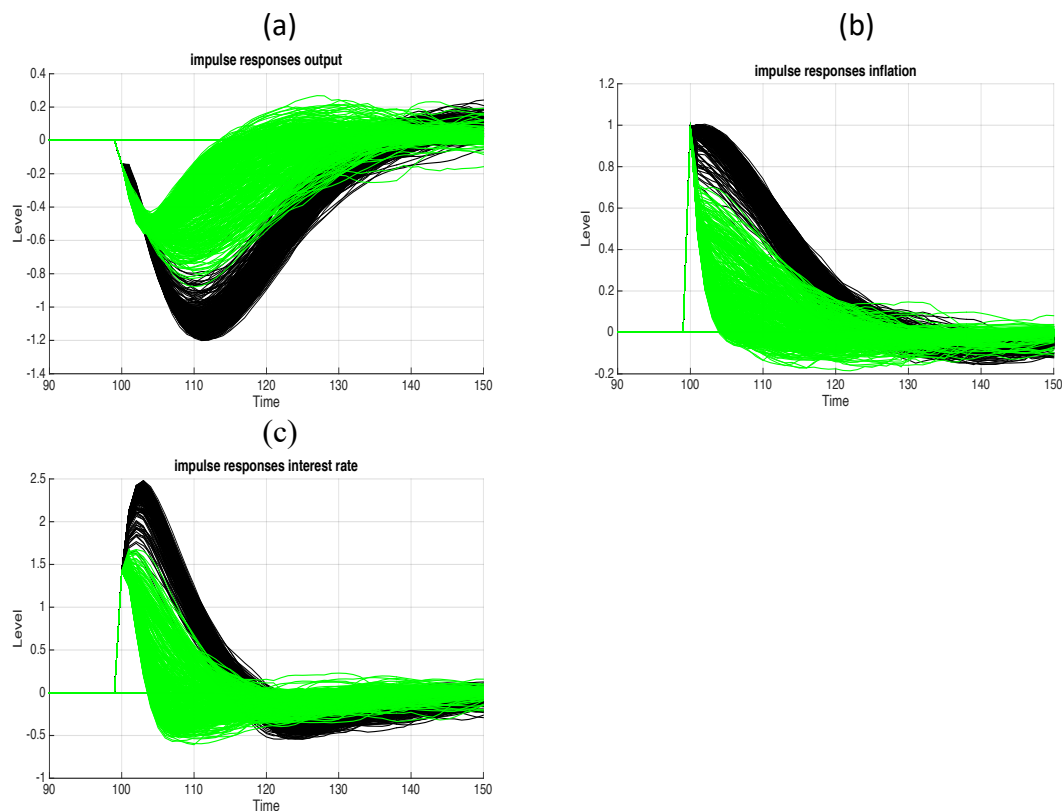

This procedure also implies that at the moment the shock occurs the system is out of equilibrium. Thus, each of the 1000 impulse responses will have as a starting point a different disequilibrium. Put differently, the initial conditions each reflect different initial disequilibria. We will show that this has important implications for the subsequent trajectories the impulse responses take.

### ***3.1 Impulse response to supply shocks***

We first discuss the impulse responses to a supply shock. We will consider a large shock which we define as a 10 standard deviation shock. This is a truly large shock, but it corresponds to the size of the shock observed in early 2020 when GDP dropped by 10% to 20% in many countries as a result of the worldwide shutdown of production. The shock produced by the financial crisis of 2007-08 was of a similar order of magnitude. In section 5 we produce a sensitivity analysis with respect to the size of the shocks. There we establish that shocks with standard deviations of 3 or more broadly reproduce the results reported in this section.

We present the 1000 impulse responses to a supply shock in Figure 1. A first thing to note is the large differences in the trajectories of the endogenous variables after the supply shock. Over time these impulse responses tend to converge, but it takes a long time for convergence to be reached. We observe the existence of two trajectories. The first one, a “good” trajectory (colored green), implies a relatively small decline of the output gap and a relatively quick return to the steady state value; the second trajectory, a “bad” one (colored black), follows a very deep decline in output and a slower recovery. A similar good and bad trajectory is detected in the impulse responses of inflation with a good trajectory of rapid declines in inflation and a bad trajectory characterized by a slower decline in inflation. These two trajectories seem to be related to the interest rate trajectory where we observe a bifurcation immediately after the shock into a (good) trajectory of quickly declining interest rate and a (bad) trajectory where the interest rate continues on an increasing path to start a decline only after 4 periods. We also note a wider variation of the individual impulse responses in the good trajectories as compared to the bad trajectories.

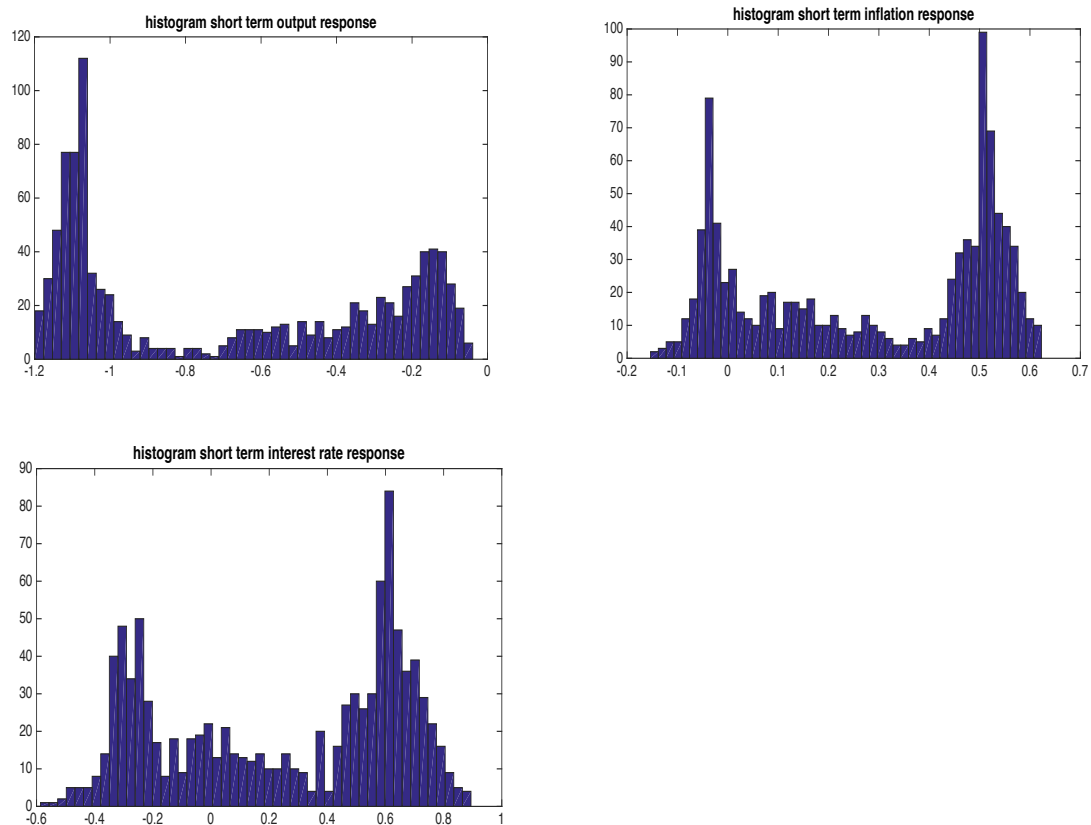

**Figure 1: Impulse responses to a large supply shock (10 std)**

The existence of two distinct trajectories can also be illustrated by presenting the distribution of the responses of the output gap in period 12 after the shock. This is obtained by taking a cross-section of the impulse responses of the output gap from Figure 1 at a particular period. Here we select period 112 (which corresponds to 12 quarters after the shock). We then plot the frequency distribution of the 1000 these impulse responses. We show the results in Figure 2.

We observe a clearly bi-modal distribution with peaks around -1.1 and -0.1 in the case of the output gap. We do the same for inflation and interest rates. For inflation, the peaks are around 0 and 0.5. This bimodal structure is associated with a bimodal structure of the interest rate with one peak at -0.3 and another at 0.6. We will come back to give an interpretation for the existence of bi-modal structure of the distribution of the impulse responses. We will then also discuss the importance of initial conditions. It will be shown that the initial conditions determine which trajectory is taken.

**Figure 2: Frequency distribution of impulse responses (12 periods after shock)**

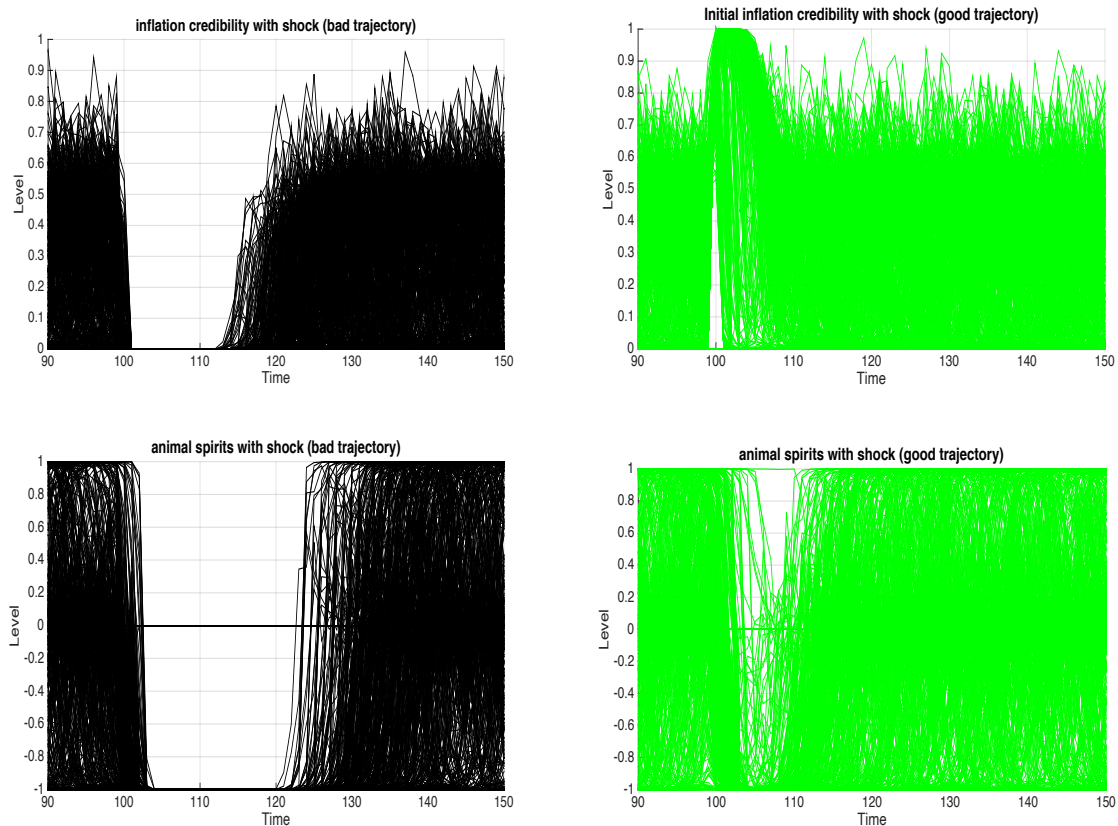

How are these trajectories connected to our measures of trust? We show the answer in Figure 3. This presents the evolution of the animal spirits and credibility before and after the supply shock in period 100. Since we run the model 1000 times we obtain 1000 trajectories for these two variables. We have split these trajectories into two: one corresponding to the bad trajectories and one from the good trajectories obtained in Figure 1. They are presented side by side for both the inflation credibility and animal spirits. Let us concentrate first on the inflation credibility. We observe something remarkable. Very soon after the supply shock inflation credibility drops to zero in all the bad trajectories. Thus, when the economy is in a bad trajectory this coincides with a collapse of credibility of the central bank. No single agent trusts the central bank anymore: the fraction of agents that use the inflation target as their forecasting rule drops to zero and they all use the extrapolative rule to make inflation forecasts. This feature is absent in the good trajectories. As will be shown later, these good trajectories are obtained when prior to the shock the inflation credibility of the central banks was very high.

We obtain a similar result with animal spirits. When the economy is pushed into a bad trajectory animal spirits drop to -1, i.e. all agents have a pessimistic outlook on the future of economic

activity. In the good trajectory we also observe some deterioration of animal spirits but this is much less extreme and much shorter.

**Figure 3: Trust: Inflation credibility and animal spirits with large supply shock**

### 3.2 Why do bifurcations occur?

The question that arises now is why the bifurcations occur. This is the question we want to analyse in this section. From Figure 3 we observe the following. When the supply shock is large the bad trajectory is characterized by the fact that immediately after the shock we obtain a limit solution, i.e. the inflation credibility drops to zero and animal spirits drop to -1. This means that the mean reverting processes in the expectations formations are switched off and only the extrapolating dynamics is left over. This creates a destabilizing dynamics that keeps the output gap low and the inflation high. For example, when credibility is zero, there are no agents anymore who expect the inflation to return to the target set by the central bank. As a result, the inflation dynamics is driven by extrapolative behaviour. The same holds for the output gap.

There is also the role played by initial conditions. In section 4 we analyse this role more rigorously. Anticipating on this analysis we can describe the role of initial conditions as follows. In order to get stuck into this bad trajectory, the initial conditions must be bad, i.e. high inflation expectations and low output. These bad initial conditions make it possible for the large negative shock to push the system towards the limits of zero credibility and extreme pessimism. In contrast when the initial conditions are favorable (low inflation expectations and optimism about the economy) the same negative supply shock does not push credibility and animal spirits against its limits. Mean reverting processes continue to do their work of softening the impact of the supply shock and one ends up in a good trajectory. Thus, favourable initial conditions work as a buffer preventing large shocks from hitting the boundaries and preventing a collapse of trust.

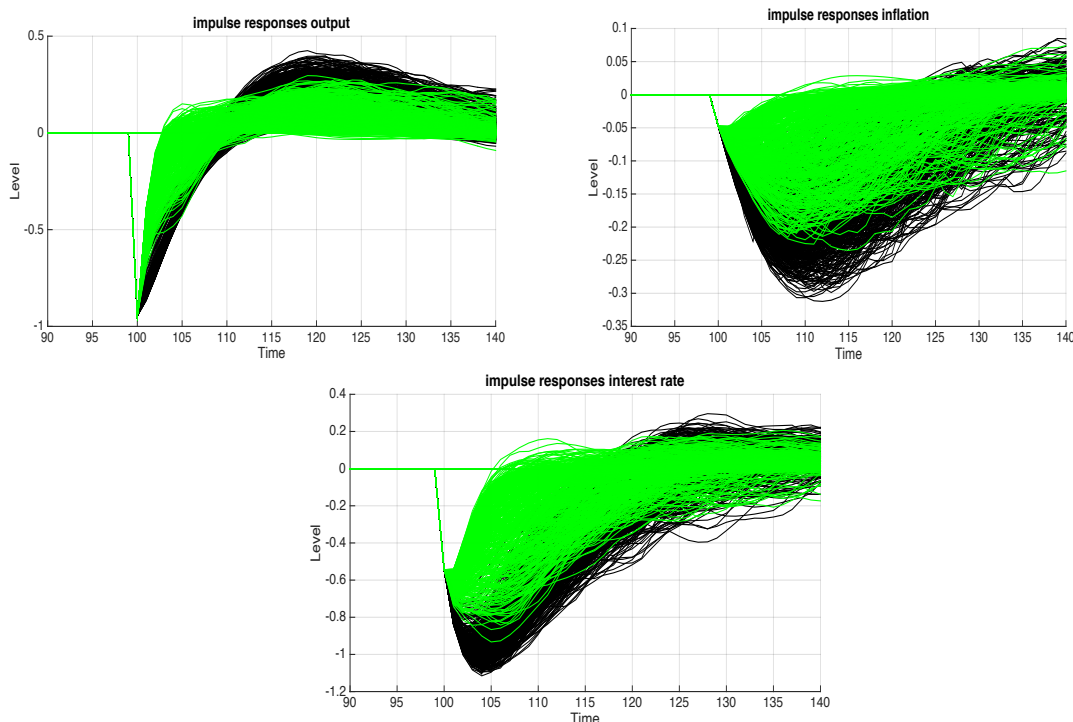

Another way to interpret these results is as follows. Large shocks that arise under unfavorable initial conditions lead to a loss of trust; both a loss of trust in institutions (the central bank) and a loss of trust about the future (pessimism). In fact, as figure 3 shows one can conclude that a large shock can lead to a complete breakdown of trust. This intense loss of trust amplifies the negative effects of the supply shock. Thus, trust is key in smoothly returning the economy to equilibrium. Trust allows mean reverting dynamics to do its work to bring the economy back to equilibrium. Conversely, absence of trust makes the economy less resilient to absorb large exogenous shocks. When trust is absent, the economy is adrift lacking an anchor that is needed to stabilize the economy after a shock.

### ***3.3 Impulse responses to demand shocks***

We now turn to the impulse responses to a large negative demand shock. We show the results in Figures 4. Comparing this with Figure 1 we find the following results. The large demand shock leads to a similar but less pronounced bifurcation of the output trajectories into a good (green) and a bad one (black). In the good trajectory output returns relatively quickly to the steady state; in the bad trajectory the recovery after the shock is slower. This seems to be related to a similar bifurcation of the interest rate trajectories.

**Figure 4: Impulse responses to a large demand shock (10 std)**

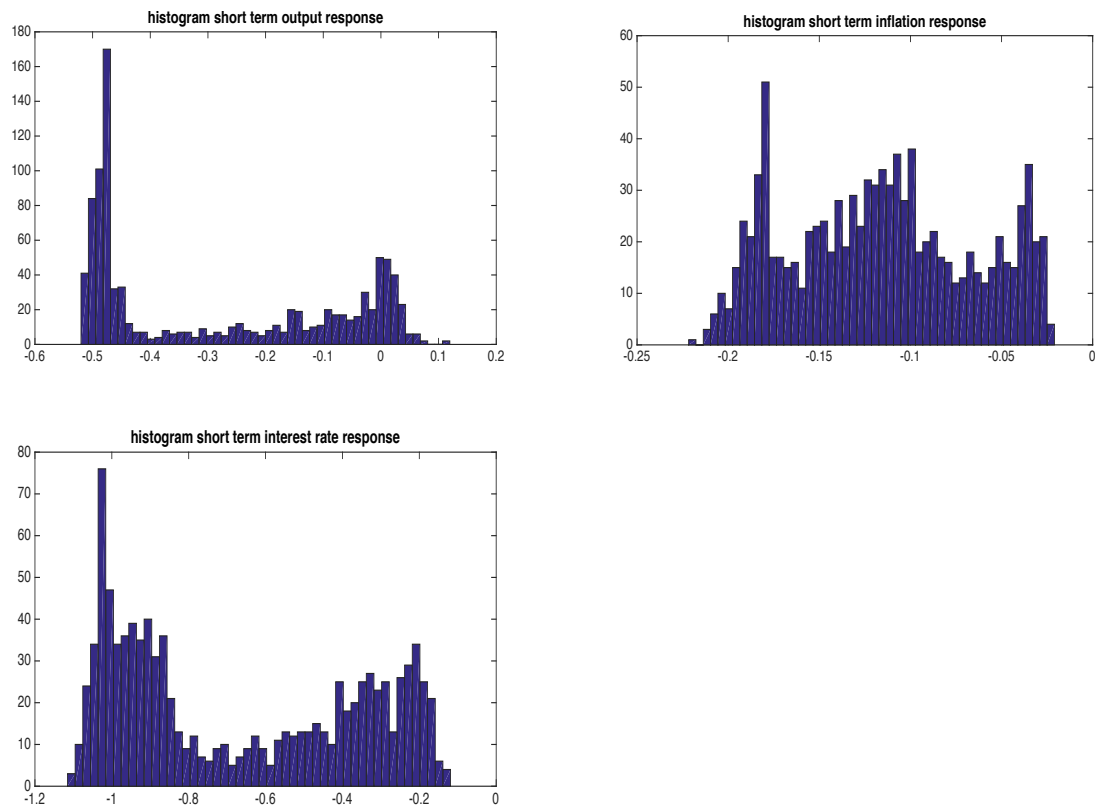

One difference with the supply shock is that the output gap tends to return to the steady state much quicker after the demand shock than after the supply shock. This is related to the fact that in contrast to a supply shock, a demand shock does not put the central bank in a dilemma situation. Both output and inflation decline and therefore give an unequivocal signal to the central bank that the interest rate should decline. This contrasts with a supply shock that produces an increase in inflation and a decline in output (stagflation). This creates a mixed signal for the central bank: the increase in inflation signals a required interest rate increase and the decline in output a required interest rate decline.

We also show the distribution of the responses of the output gap, inflation and interest rate in period 4 after the shock (Figure 5). We chose 4 quarters because after the demand shock the output gap is much quicker to return to its long-term equilibrium than after the supply shock. One way to put this difference is that the short-term is much shorter after a demand shock than after a supply shock.

Like in the case of the supply shock, we observe a bi-modal distribution of the impulse responses 4 quarters after the shock. This bi-modal structure is less pronounced than after the supply shocks though. Again, the interpretation is that the demand shock does not push the central bank in a dilemma situation allowing it to pursue an unequivocal policy of interest rate reduction.

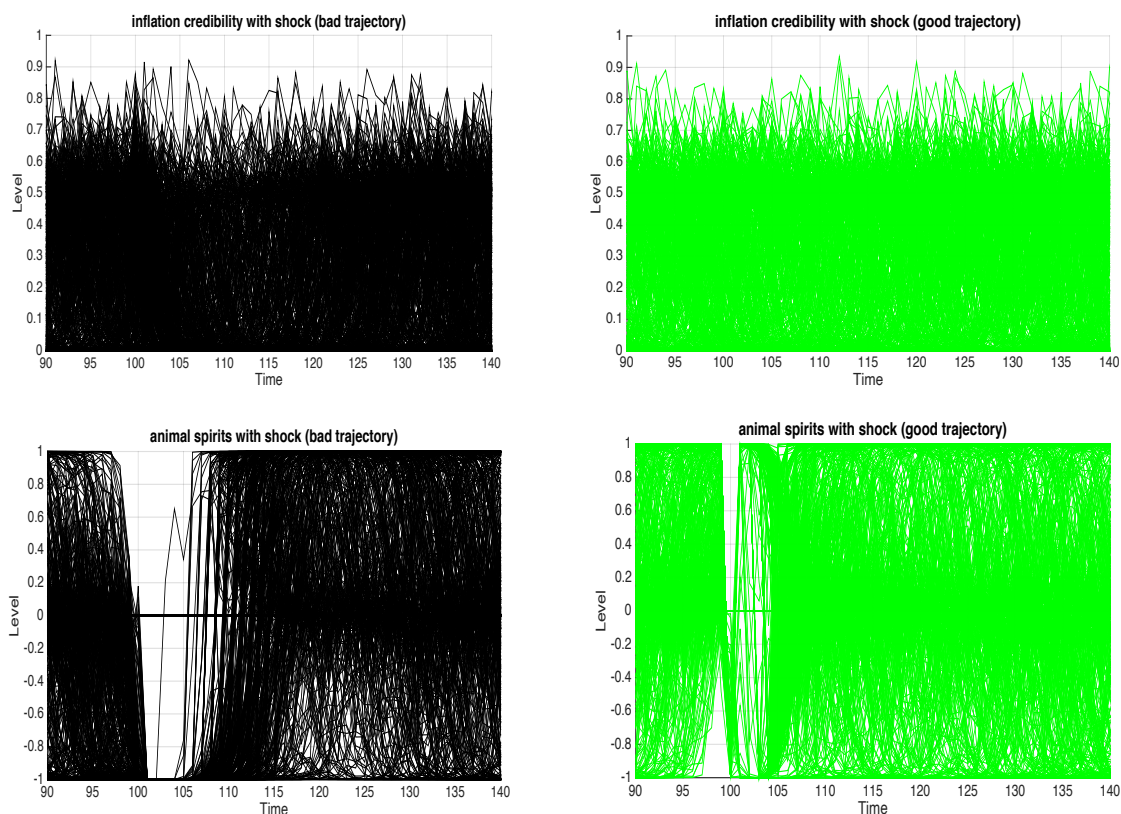

**Figure 5: Frequency distribution of impulse responses (4 periods after shock)**

What happens with our measures of trust after the demand shock? We show the answer in Figure 6. Following the negative shock in demand we observe that trust in the central bank is very little affected in the bad trajectory and not at all in the good trajectory. Bad and good trajectories in this demand shock scenario are associated mainly with negative developments in trust towards the future of economic activity. We observe that following the negative demand shock there is a strong decline in animal spirits reaching the limit of -1 and therefore creating a dynamics of deflation because agents extrapolate extreme pessimism in this bad trajectory. In the good trajectory these deflationary forces are much less pronounced and shorter-lived.

We conclude that after a negative demand shock the central bank does not suffer much from a loss of trust. This is related to the fact that after the demand shock the central bank is not pushed into a dilemma situation that prevents it from pursuing a clear interest rate policy aimed at boosting the economy and bringing the inflation rate closer to its target. The loss of trust is concentrated in the goods market. When initial conditions are unfavorable, i.e. when there is initially a lot of pessimism, the demand shock will push this pessimism to its extremes, thereby intensifying the pessimism further because everybody extrapolates this pessimism into the future. When initial conditions are favorable, this deflationary mechanism is dampened.

**Figure 6: Trust: Inflation credibility and animal spirits with large negative demand shock**

### 3.4 Robustness analysis

The results discussed up to now use the point estimates of the parameters of the model as given in Table 1. It will be interesting to know how sensitive these results are to the choice of these numerical values. To do so we perform a Monte Carlo experiment in which the parameters in Table 1 vary within a certain range. We set this range as + and – 50% of the point estimates and assumed a uniform distribution (For example:  $a_1$  varies uniformly between 0.25 and 0.75). We then computed 1000 impulse responses following a negative supply shock, where for each impulse response we choose the parameter values randomly within that range. We show the impulse responses obtained from this exercise in Figure 7.

We observe the same bifurcations of the impulse responses into a good and bad trajectory. This can be observed from both the results in the time domain and the frequency domain. Similarly, trust appears to be disappearing suddenly in the bad trajectory in the same way as we documented earlier. We have performed similar Monte Carlo experiments showing that our results are equally robust after a demand shock. These robust results justify that we may continue to use the parameters in Table 1 in our other analyses.

**Figure 7: Large negative supply shock- Monte Carlo experiment**

#### 4 The power of initial conditions

How do the initial conditions affect the output and inflation trajectories following the demand and the supply shocks? This is the question we analyze in this section. We have already hinted at the importance of initial conditions in an informal way. Here we do this more formally. We will present simple charts, and in Appendix 3 we turn to the use of econometric methods.

## ***4.2 Supply shocks***

We start with the supply shocks. In Figure 8 we present one of the initial conditions, (i.e. inflation expectations prevailing just before the shock), on the horizontal axes, and the output gap and inflation 12 periods after the supply shock on the vertical axes. It is striking to find that after a large supply shock the initial expectations of inflation appear to be a very good predictor of the subsequent trajectories of the output gap and inflation. More specifically, when initially inflationary expectations exceeded the central bank's inflation target (normalized at 0) the output gap multiplier after 12 periods settles around -1.1. In other words, the subsequent output trajectory is always the bad one, i.e. the output gap is pushed down further as shown in Figure 1. In contrast when initially the inflation expectations are below the central bank's inflation target, the output gap multiplier after 12 periods settles close to -0.2 (but with a relatively large variance). Thus, in this case the subsequent trajectory is always a good one. In Figure 1 this corresponds to the (green) trajectory that quickly leads the output gap to return to equilibrium.

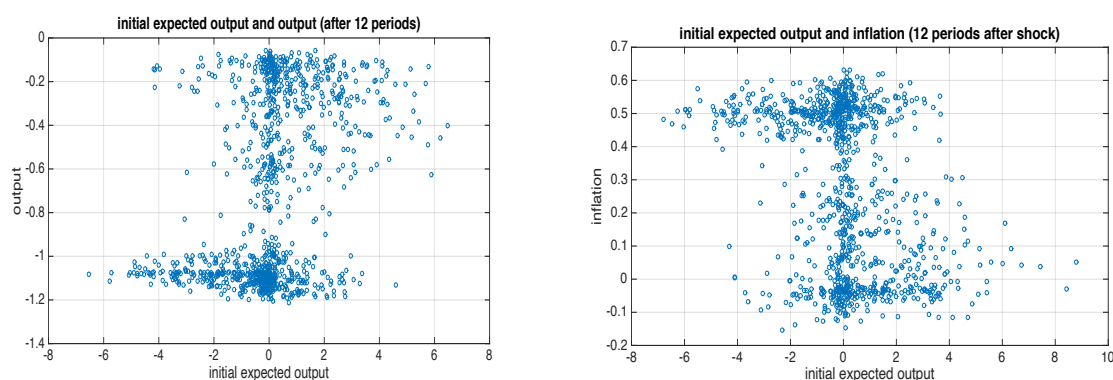

The initial expectations of inflation have an equally strong predictive power for subsequent inflation. Favorable initial inflation expectations (negative numbers) lead to the trajectory of low inflation 12 periods later. With unfavorable inflation expectations the economy is forced onto the high inflation trajectory.

The predictive power of the initial output forecasts is less strong, as can be seen from Figure 9. Optimistic forecasts of the output gap appear to lead to both a good and bad subsequent trajectory. Similarly optimistic output forecasts lead to both low and high inflation outcomes. In the econometric analysis reported in Appendix 3 we show that initial output gap forecasts have some, but limited, predictive power. This econometric analysis allows us to estimate the predictive power of initial conditions (both the large and small supply shocks). This econometric analysis confirms the results discussed in this section.

**Figure 8: Initial inflation expectations, and output gap and inflation 12 periods after shock**

**Figure 9: Initial output expectations, and output gap and inflation 12 periods after shock**

What is the underlying mechanism that explains the strong power of the initial inflationary expectations to predict the subsequent trajectory of the output gap and inflation when the supply shock is large? To answer this question, we have to analyse the reactions of the central bank to the supply shock. To do so it is useful to turn to Figure 1 again.

We note the following. There is a quick bifurcation in the interest rate path after the shock. One path goes up; the other goes down. The upward interest rate path corresponds to the high inflation initial condition. This unfavourable initial condition has the effect of keeping the inflation rate at a high level after the supply shock. As a result, the central bank that attaches a relatively high weight on inflation in the Taylor rule feels obliged to raise the interest rate. This in turn pushes the output gap further down. The economy is pushed into a bad trajectory because the unfavourable inflation expectations that existed prior to the shock force the central bank to tighten up after the shock, thereby enhancing the downturn in output.

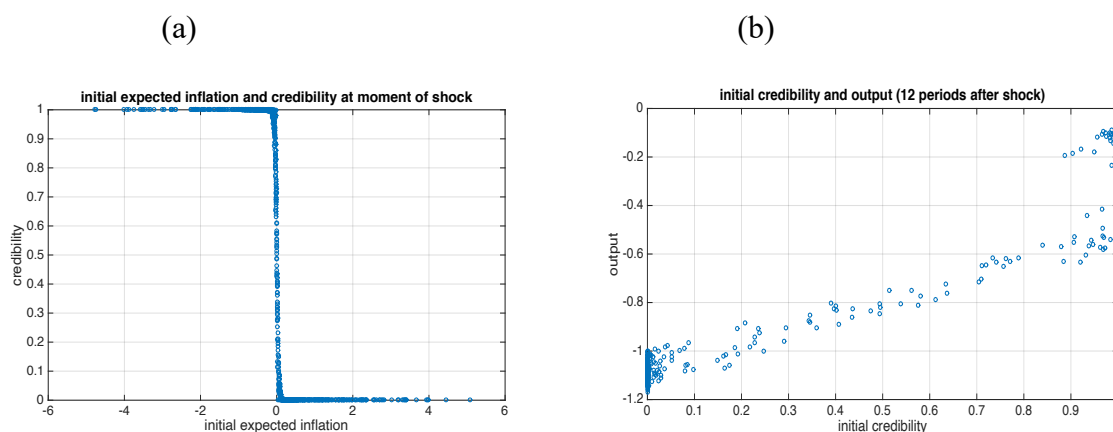

In contrast, when the inflationary expectations are initially favourable (below the inflation target), the upward movement of the inflation immediately after the shock remains subdued. As a result, the central bank observing a relatively favourable inflation outcome reacts by

reducing the interest rate to deal with the negative effect of the supply shock on output. This mitigates the negative output effect of the supply shock and pushes the economy onto the good trajectory with a quick return of the output gap to its equilibrium level. Here again the initial favourable inflation expectations tend to reduce the inflation effect of the supply shock “freeing the hands” of the central bank to fight the decline in output by a reduction of the interest rate.

The previous analysis can be complemented by introducing the inflation credibility of the central bank that as will be remembered is measured by the fraction of agents that use the announced inflation target as their forecasting rule. With 100% credibility this fraction is 1, i.e. all agents rely on the inflation target to forecast next period’s inflation. With 0% credibility no agents use the inflation target as their forecasting rule; instead, all of them use extrapolation of the past inflation rate as their forecasting rule.

We now find the following results, represented in Figure 10. Figure 10(a) shows the relation between the inflation expectations before the shock (horizontal axis) and the central bank’s credibility at the time of the shock. We observe that when in the past inflation expectations were very high, i.e. above the target, the effect of the supply shock is to reduce the central bank’s credibility dramatically to zero. This then also explains the strong increase in inflation that is driven mainly by extrapolative behaviour. The dramatic loss of credibility then also becomes a very good predictor of the subsequent decline in the output gap as is shown in Figure 10(b). We observe that when the central bank’s credibility is very low the output gap is very likely to follow the bad trajectory with a steep decline in period 12 after the supply shock.

**Figure 10: Initial inflation expectations, credibility and the output gap**

The reverse happens when the initial inflation expectations are below the inflation target. The supply shock then actually improves the central bank’s credibility and this guides the output gap into the good trajectory with a low decline in output.

### 4.3 Demand shocks

We proceed as in the previous section and show two initial conditions, i.e. inflation expectations and output gap forecasts prevailing just before the shock on the horizontal axes, and the output gap 4 periods after the demand shock on the vertical axes. We show the results in Figure 11.

In contrast with the supply shock, we now find that it is the initial output expectation that has the strongest predictive power. More precisely, when initially agents are optimistic about future output, the output gap 4 periods later clusters around 0%. In other words, initial optimism about the future business cycle forces the economy along the good trajectory after the demand shock. In contrast, when output forecasts are negative, the output gap 4 periods later settles around -0.5. Thus, pessimism about the future business cycle pushes the economy along the bad trajectory after the demand shock. Note that inflation forecasts have only limited power to predict which trajectory will be chosen.

**Figure 11: Initial inflation and output expectations, and output gap 4 periods after demand shock**

Comparing these results with the impulse responses after a large demand shock as shown in Figure 4 leads to the following paradox. The good trajectory is one where output recovers very quickly after the demand shock while at the same time the central bank quickly increases the interest rate. The bad trajectory is the one where output continues to decline after the shock while the central bank reduced the interest rate further. How can one explain this?

The answer has to do with the initial conditions, in particular with output expectations and initial output (not shown here, but to be included in the econometric analysis). When the economy is in a boom to start with (optimistic output expectations and positive output gap),

the negative demand shock has a subdued effect on output. Also inflation does not decline much. As a result, the central bank quickly restores its pre-shock policy stance. When the economy is in a recession to start with (negative output gap and pessimistic outlook) the negative shock has a much stronger negative effect on output and inflation forcing the central bank to drastically reduce the interest rate. This sharp decline then makes it possible to return to equilibrium but with a delay. Thus, it is the initial business cycle situation that determines the trajectory subsequent to the shock. The central bank is purely reactive.

## **5 Sensitivity analysis: size of the supply shocks**

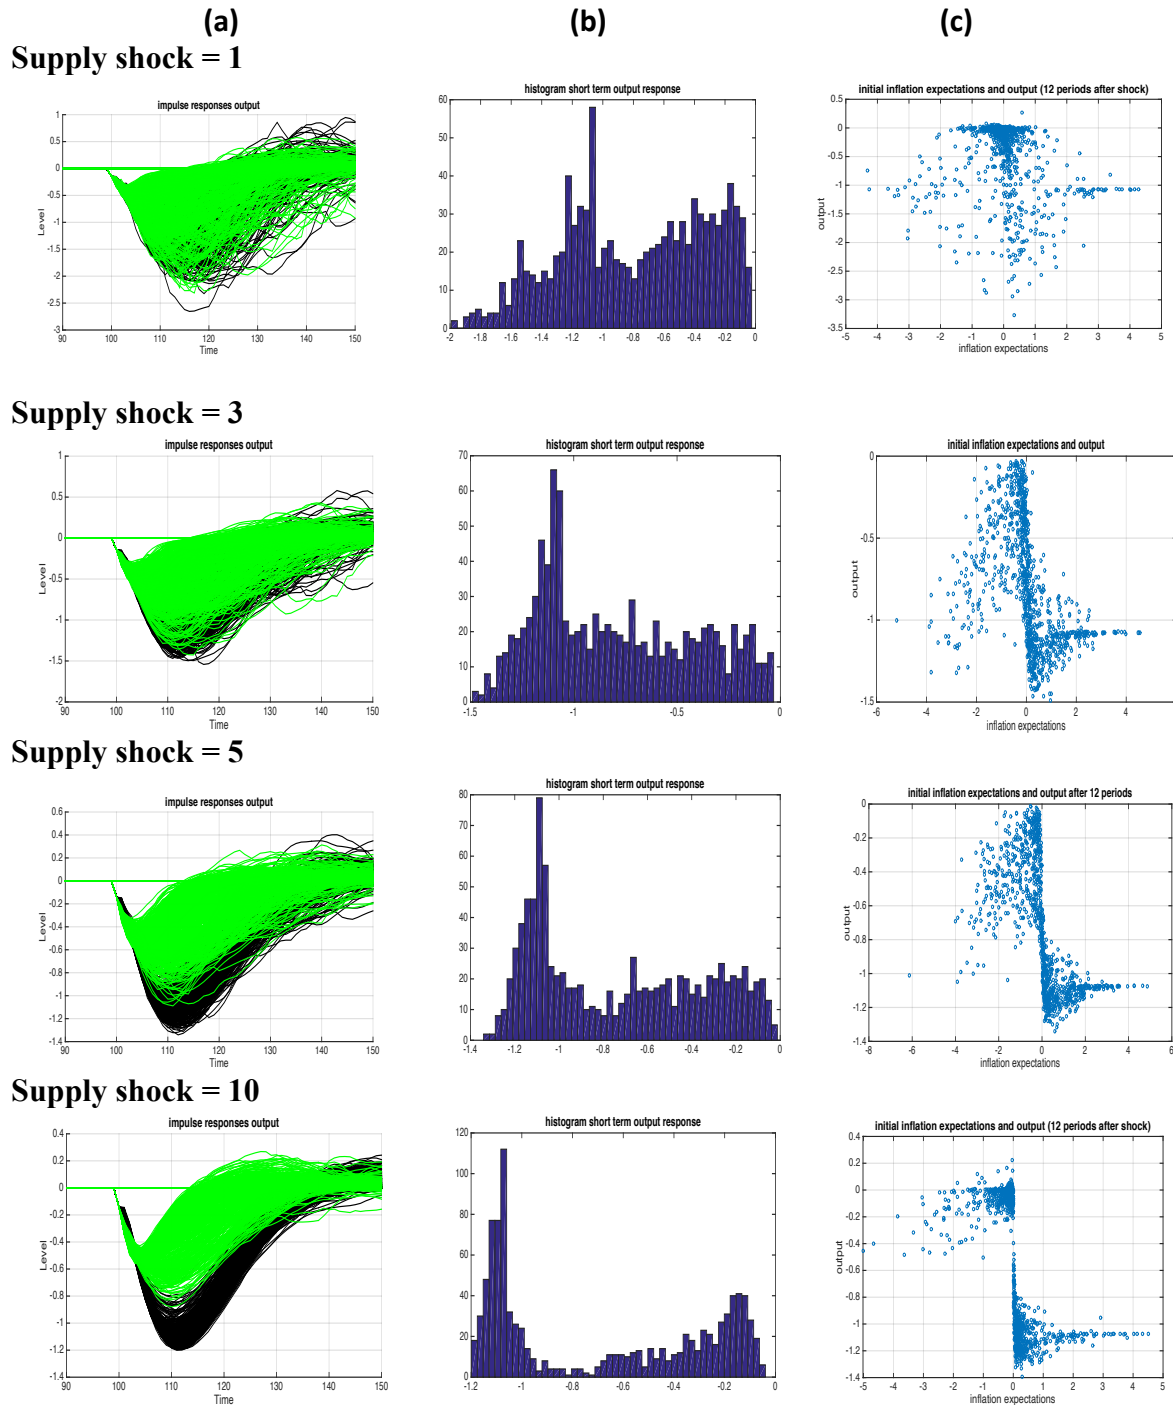

In this section we establish the size of the shocks that will trigger a bifurcation in the trajectories. We do this with a sensitivity analysis in which we allow the size of the shocks to vary. We start with a one standard deviation shock and we gradually increase the size of the shock. We present the results for the supply shock in Figure 12.

Concentrating first on the impulse responses (a) we find that as the size of the supply shock is increased, the bifurcation in the trajectories start to become visible with a shock of 3 standard deviations. This is also made clear from the (b) column in Figure 12. This shows the frequency distribution of the output response after 12 periods. We observe that from a supply shock equal to 3 on, the distribution starts showing a bi-modal distribution indicating that the impulse responses tend to bifurcate. Finally, the evidence in column (c) confirms this. With a supply shock of 3 we achieve some measure of predictability of the subsequent output responses by the initial inflationary expectations.

How can one interpret the low predictive power of initial conditions when the supply shock is small? Here is the answer. A supply shock equal to 1 standard deviation of the stochastic shocks hitting the economy is of the similar order of magnitude as the existing stochastic shocks. As a result, the initial conditions create departures from the equilibrium that have the similar order of magnitude as the supply shock. This does two things. First, it leads to a very low signal to noise ratio, the signal being the supply shock and the noise being the initial condition. As a result, the signal will tend to be overwhelmed by the noise. Second, as the initial conditions are departures from equilibrium, the supply shock has a similar magnitude as the departures from equilibrium. These initial departures from equilibrium can steer the economy in a different direction than the supply shock does. It can also be that the initial conditions and the supply shock reinforce each other. Since the forces of the initial conditions and of the supply shock

are of a similar magnitude, it becomes near impossible to separate them out by computing impulse responses. All this produces a low predictability of the initial conditions on the output trajectory after the shock. This problem of unpredictability does not occur when the supply shock is large relative to the size of the stochastic shocks, or put differently, when the signal to noise ratio is large. We obtain similar results for demand shocks (not shown here).

**Figure 12: Increasing the size of the supply shock**

There is another difference between the trajectories following large (3 standard deviation or more) and small (less than 3 standard deviations). Large shocks produce good and bad trajectories. In contrast small shocks do not produce such bifurcations in the trajectories. This has to do with the fact that small shocks do not push the trust indicators (credibility and animal spirits) against their limits. As a result, the mean reversion dynamics in forecasting is not switched off as it is following large shocks when the initial conditions are unfavourable.

## **6. The power of output stabilization: supply shock**

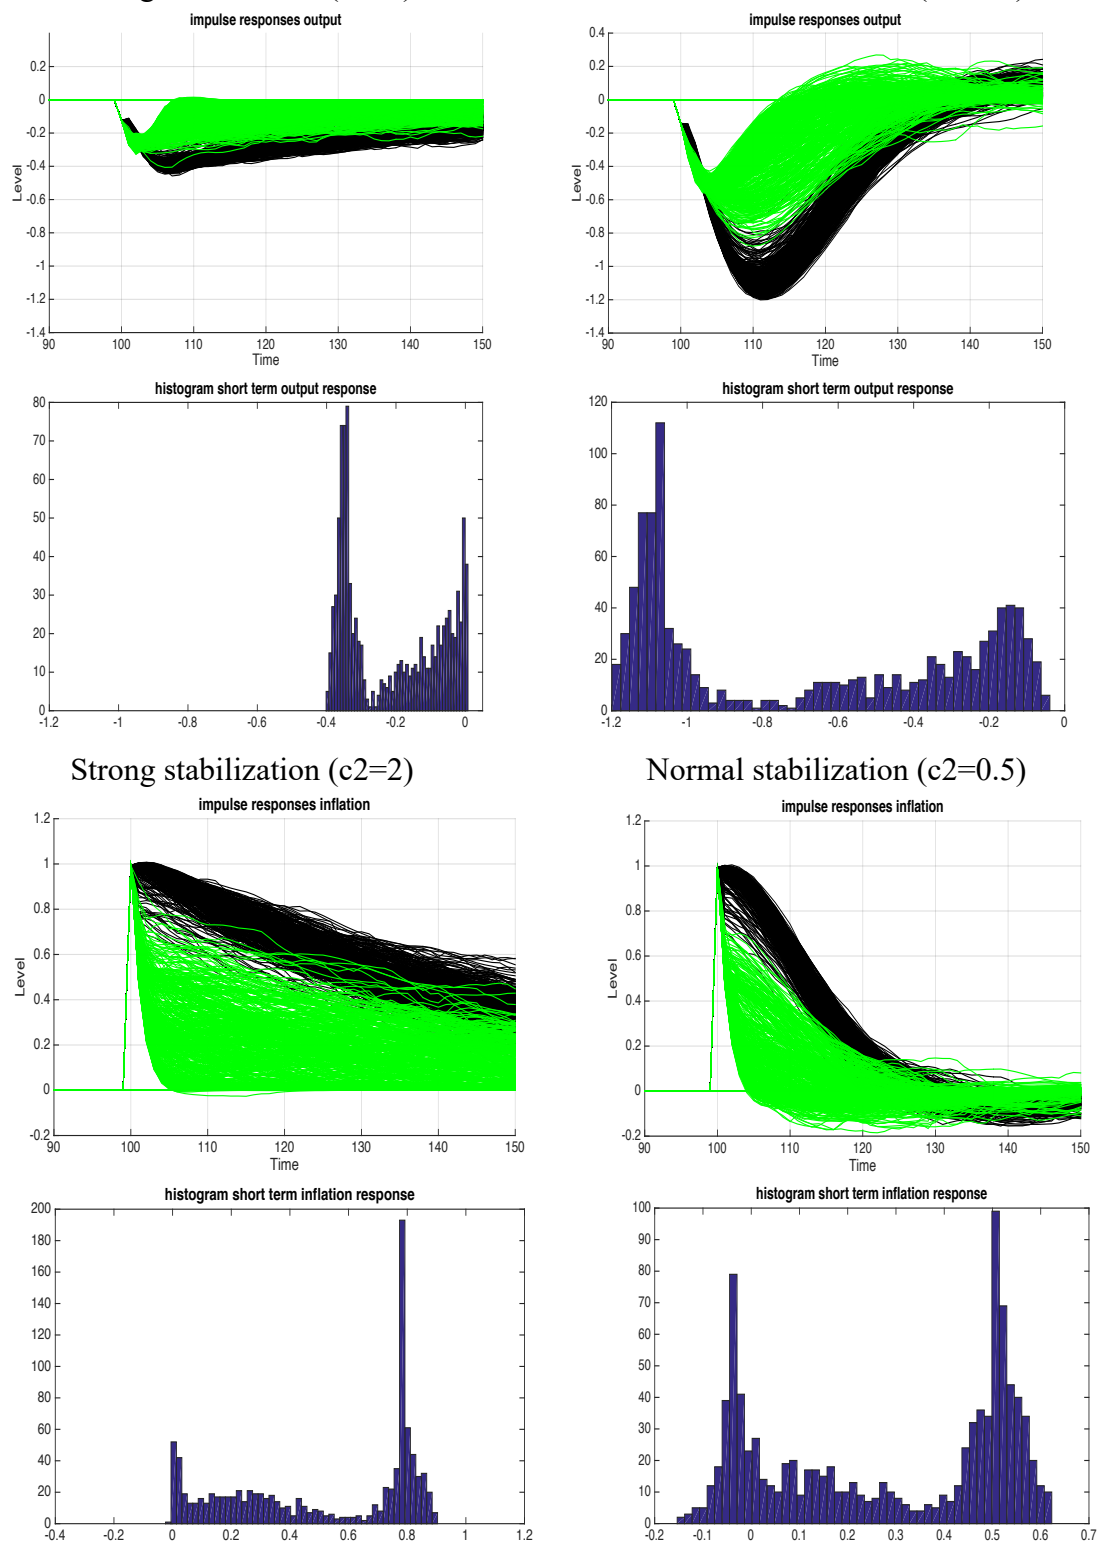

### **6.1 output gap and inflation**

In this section we study how the intensity with which the central bank stabilizes the output gap affects the transmission of large shocks. This is a relevant policy question on how strongly central bank should respond to output stabilization when setting its interest rate. As will be remembered the intensity of output stabilization is measured by the  $c_2$  parameter in the Taylor rule equations. We have set  $c_2$  routinely equal to 0.5 in the previously reported results. Here we ask the question of how a stronger stabilization effort affects the transmission of a large supply shock. We show the results in Figure 13. We distinguish two output stabilization intensities, a strong one ( $c_2=2$ ) and a normal one ( $c_2=0.5$ ). (Note that the results reported in the “normal stabilization” column are the same reported supra). The results lend themselves to the following interpretation.

First, by increasing the intensity of output stabilization the central bank ensures that the bad trajectory becomes significantly less bad. This can be seen from the impulse responses of output. Under normal stabilization there is a deep negative trajectory. This downward movement of the bad trajectory is significantly reduced under strong stabilization. The good trajectory is pretty much unchanged when stabilization is strong. Another way to see this is provided by the histograms of the output gap. Under strong stabilization we observe that the peaks of the bimodal distribution are closer to each other, and that this is achieved by a movement of the “bad peak” to the right and closer to the “good peak”. Thus stronger stabilization achieves a less severe downturn in the bad trajectory.

All this comes at a price, though. When output stabilization is strong, we observe that the bad and the good inflation trajectories produce an inflation trajectory that is more protracted. In other words, stronger output stabilization leads to inflation that lasts longer after a supply shock.

**Figure 13: Transmission of large supply shock under strong and normal stabilization**

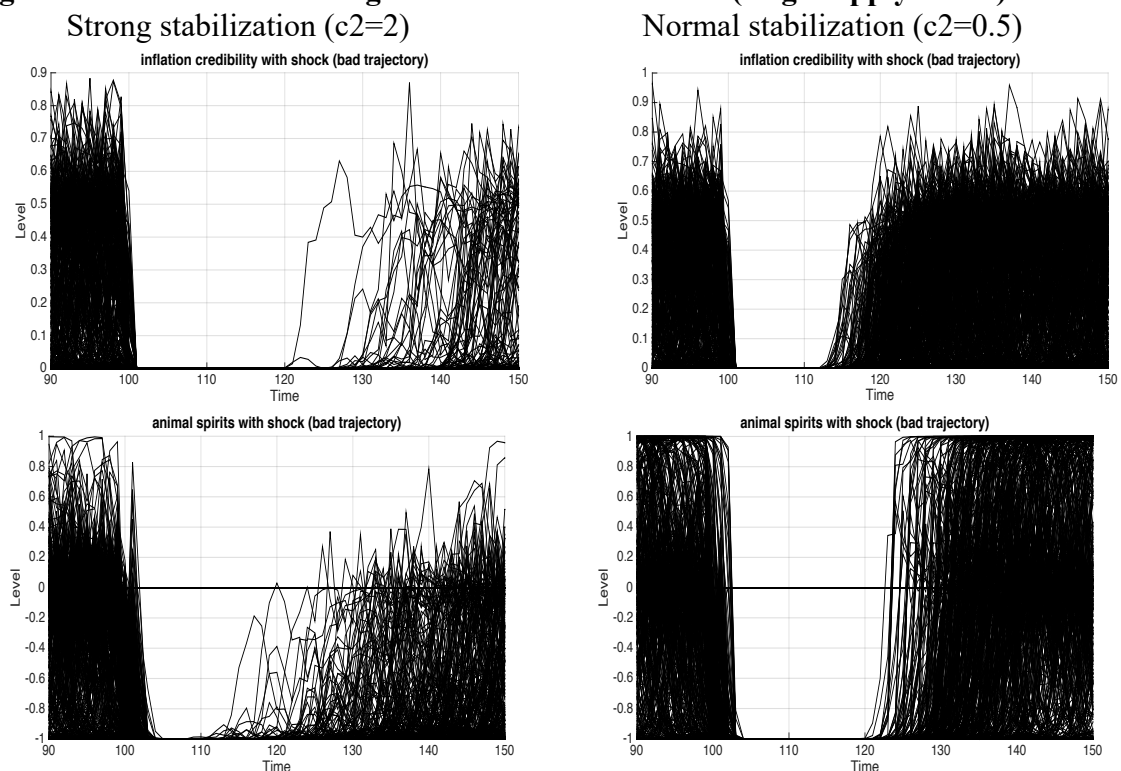

## 6.2 Output stabilization and trust

We have seen in previous sections that large shocks endanger the trust of economic agents in two dimensions, i.e. institutional (trust in the central bank) and in the economy. We also found that a breakdown of trust in these two dimensions is more likely when large supply shocks hit the economy, and less so when large demand shocks occur. How can the central bank affect trust after large supply shocks? This is the question we pursue in this section.

We answer this question by analyzing how the degree of output stabilization (measured by the Taylor parameter,  $c_2$ ) affects trust. We focus on a large negative supply shock and compare the case of “normal” output stabilization and “strong” output stabilization. As in the previous section, in the first case we set  $c_2 = 0.5$ , in the second case we set  $c_2=2$ . We show the results in Figure 14. We observe that when the central bank increases its ambition to stabilize output ( $c_2$  increases from 0.5 to 2) trust declines significantly after the supply shock. We see this from the fact that after the supply shock inflation credibility drops to 0 in both cases, but it remains stuck at zero longer when output stabilization is strong. The same holds with animal spirits after the shock. Thus, when large negative supply shocks occur a central bank that aggressively pursues output stabilization will suffer a loss of trust longer than a central bank that pursues output stabilization more cautiously. In addition, trust in the economy (pessimism about future recovery) will then remain a feature for a longer time.

**Figure 14: Trust under strong and normal stabilization (large supply shock)**

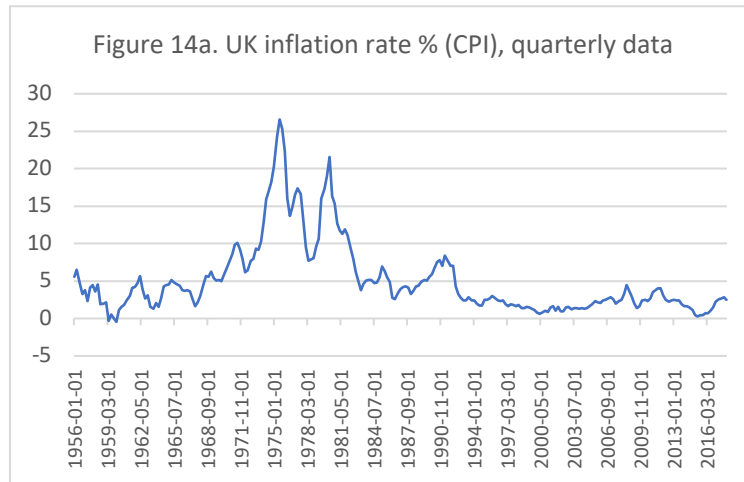

## *7. Supply shocks: some historical perspective*

Our results have some relevance to understand the experience of the 1970s with the supply shocks and the recent covid supply shock. Preceding the supply shocks of the 1970s there had been a buildup of inflation and inflationary expectations. See Figures 15a and 15b showing the US and UK inflationary experiences. Our model predicts that with these initial conditions, the recovery would take a long time. This is also what happened for many countries with a prior history of significant inflation, especially after the second oil shock of 1979. According to the World Bank (2021) the world GDP growth rate took five years to return to its pre-1979 level of 4.2%. This growth rate was only reached in 1984 again. The trajectory of this protracted recovery also followed the prediction of our model: given the inflationary environment the supply shock of 1979 “forced” many central banks, in particular the US Federal Reserve under Paul Volcker, to raise the interest rates thereby intensifying the economic downturn. See also Bernanke et al. (1997) who find that the negative output effects of the supply shock (oil shock) of the 1970s were the result of the restrictive monetary policies that the supply shock triggered.

The Covid supply shock of 2020 was preceded by a period of low inflation and low inflationary expectations in most industrialized countries (see Figure 2 for the Eurozone experience). Our model predicts that this should make a quick recovery possible, mainly because the central banks did not worry about the inflationary consequences and therefore could actually follow expansionary monetary policies. It appears today that a relatively quick recovery occurred. We show this in Figure 15 which presents the real growth rates of GDP in the Eurozone. We observe that indeed the recovery in 2021 was spectacular. Figure 16 shows the same measure of trust in the ECB that we presented in Figure 1. This is the percentage of EU citizens that respond they have confidence in the European Central Bank. We observe that after the financial crisis there was a steady increase in trust in the ECB. As a result, when the pandemic shock occurred the hands of the ECB were freed to pursue a highly stimulatory monetary policy. This, together with expansionary fiscal policies made it possible for the economic recovery to be very fast. Unfortunately, in 2022 a new shock, the Ukraine war occurred...

The previous discussion implies that history matters. A history of high inflation and expectations of inflation condition the impact of a supply shock and is likely to produce bad

outcomes of this shock. In contrast a history of price stability makes it possible for the economy to follow a more benign trajectory after the same supply shock<sup>4</sup>.

Source: Federal Reserve Bank of St Louis

Source: Eurostat

<sup>4</sup> This conclusion is also confirmed indirectly by Bobeica, et al. (2020) and (2021). These authors find that the wage price spiral tends to be more intense after a supply shock when initially high inflation expectations prevailed in the Eurozone and the US.

Source: Eurobarometer

Note: Trust is defined as the percentage of EU-citizens declaring that they have confidence in the ECB

## 8. Conclusion

In this paper we have analyzed the importance of trust in the transmission of demand and supply shocks in the economy. We have focused on two dimensions of trust. The first one is institutional. It is related to the credibility of the inflation target announced by the central bank, and we measured this by the fraction of agents using the inflation target as their prediction rule for inflation. The second one is trust in the future, measured by an index of optimism (pessimism) about future economic activity.

In order to analyze the importance of trust we used a behavioural macroeconomic model that is characterized by the fact that individuals lack the cognitive ability to understand the underlying model and to know the distribution of the shocks that hit the economy. In such a world it is rational for these individuals to use simple forecasting rules (heuristics) and to subject these rules to a regular fitness test. As a result, these agents frequently switch to the best performing rule. This creates a dynamics of booms and busts driven by waves of optimism and pessimism (animal spirits). It is also a model that allows us to give a quantitative content to our two measures of trust.

Our main results can be summarized as follows. Focusing on negative supply shocks we find, first, that when the negative supply shock is sufficiently large (3 standard deviations or more) there exist two trajectories of output. The first one, a “good” trajectory, implies a relatively small decline of the output gap and a relatively quick return to the steady state value; the second trajectory, a “bad” one, follows a deep decline in output and a slower recovery. A similar

bifurcation between good and bad trajectories is detected in the impulse responses of inflation generating a good trajectory of rapid declines in inflation and a bad trajectory characterized by a slower decline in inflation.

Second, trust follows similar good and bad trajectories. We find that in all the bad trajectories of output and inflation, the credibility of the central bank drops to zero. Thus, when the economy is in a bad trajectory this coincides with a collapse of credibility. No single agent trusts the central bank anymore: the fraction of agents that use the inflation target as their forecasting rule drops to zero and they all use the extrapolative rule to make inflation forecasts. At the same time trust in the future of economic activity (animal spirits) also drops to its minimum value (extreme pessimism). These features are absent in the good trajectories. When the economy is in a good trajectory of output and inflation our two measures of trust do not decline. This makes the good trajectory possible.

Third, we find that initial conditions matter a great deal in determining which trajectory will be chosen. In order to get stuck into a bad trajectory, the initial conditions must be bad, i.e. there must be high inflation expectations and pessimism about future output. These bad initial conditions make it possible for the large negative supply shock to push the system towards the limits of zero credibility and extreme pessimism. As a result, the mean reverting processes in the forecasting behaviour of agents are switched off and forecasting is purely extrapolative. This means that along this bad trajectory the forces that push towards a return to equilibrium are weak.

In contrast when the initial conditions are favorable (low inflation expectations and optimism about the economy) the same negative supply shock does not push credibility and animal spirits against its limits. In that case mean reverting processes in the forecasting behaviour continue to do their work of softening the impact of the supply shock and one ends up in a good trajectory. Thus, favourable initial conditions work as a buffer preventing large shocks from hitting the boundaries and preventing a collapse of trust.

Summarizing these three results, one can conclude that large negative supply shocks that arise under unfavorable initial conditions lead to a loss of trust; both a loss of trust in institutions (the central bank) and a loss of trust about the future (pessimism). This intense loss of trust amplifies the negative effects of the supply shock. Thus, trust is key in smoothly returning the economy to equilibrium. Trust allows mean reverting dynamics to do its work to bring the economy back to equilibrium. Conversely, absence of trust makes the economy less resilient

to absorb large exogenous shocks. When trust is absent, the economy is adrift lacking an anchor that is needed to stabilize the economy after a shock.

The results obtained for large negative demand shocks are similar to the ones obtained for large supply shocks, i.e. emergence of good and bad trajectories, correlation with trust and importance of initial conditions in determining the nature of the subsequent trajectories. There is a difference though. In general, the loss of trust in the central bank is much less pronounced when a negative demand shock occurs. This has to do with the fact that after a negative demand shock the central bank is not put into a dilemma situation (as it is after a negative supply shock). As a result, the central bank can keep inflation closer to its target more effectively and maintains much of its credibility.

We also performed a sensitivity analysis to find out how large supply and demand shocks have to be to generate good and bad trajectories that can be predicted by initial conditions and that are highly correlated with trust. We found that for shocks of 3 standard deviations or more the conditions exist to generate bifurcations in the impulse responses to these shocks. When shocks are small (less than 3 standard deviations) this bifurcation does not emerge. Initial conditions still matter a great deal to determine the trajectories after the shock, but these initial conditions do not have much predictive power.

Finally, we found that output stabilization by the central bank matters. Negative supply shocks create important threats to trust in the central bank and in the economy, all the more so when central banks pursue aggressive policies of output stabilization. Trying harder to stabilize output after a supply shock only makes matters worse.

Our results have some relevance to understand the experience of the 1970s with the large supply shocks and the recent covid supply shock. Preceding the supply shocks of the 1970s there had been a buildup of inflation and inflationary expectations. Our model predicts that with these initial conditions, the recovery would take a long time. This is also what happened for many countries with a prior history of significant inflation, especially after the second oil shock of 1979. According to the World Bank(2021) the world GDP growth rate took five years to return to its pre-1979 level of 4.2%. This growth rate was only reached in 1984 again. The trajectory of this protracted recovery also followed the prediction of our model: given the inflationary environment the supply shock of 1979 “forced” many central banks, in particular the US Federal Reserve under Paul Volcker, to raise the interest rates thereby intensifying the economic downturn.

The Covid supply shock of 2020 was preceded by a period of low inflation and low inflationary expectations. Our model predicts that this should make a quick recovery possible, mainly because the central banks did not worry about the inflationary consequences and therefore could actually follow expansionary monetary policies. It appears today that a relatively quick recovery occurred during 2021, until unfortunately a new shock occurred, the Ukraine war.

Our analysis implies that history matters. A history of high inflation and expectations of inflation condition the impact of a supply shock and is likely to produce bad outcomes of this shock. In contrast a history of price stability makes it possible for the economy to follow a more benign trajectory after the same supply shock.

## Appendix 1. Microfoundations of the basic behavioral model

We show that the aggregate demand and supply equations used in the main text can be micro-founded on individual utility maximization of households and profit maximization of firms.

### 1. Aggregate demand

Let us start by modeling the demand side of the model. This will be based on the maximization of individual's utility of consumption over an infinite horizon. The individual consumer,  $i$ , maximizes the following function over an infinite horizon:

$$E_0 \sum_{t=0}^{\infty} \beta^t U(C_t^i, N_t^i) \quad (\text{A1})$$

where  $\beta$  is discount factor,  $U$  is the utility function which is assumed to have the same form every period and every agent,  $C_t^i$  is consumption of agent  $i$  in period  $t$  and  $N_t^i$  is hours worked by agent  $i$ .

The budget constraint faced by consumer  $i$  is:

$$P_t C_t^i + Q_t B_t^i \leq B_{t-1}^i + W_t N_t^i - T_t \quad (\text{A2})$$

where  $B_t^i$  is the quantity of one period discount bond purchased by agent  $i$  in period  $t$  and maturing in  $t+1$ ;  $Q_t$  is price of bond,  $P_t$  is the price of consumption goods,  $W_t$  is the wage rate and  $T_t$  is a lump-sum tax

First order condition for consumer's optimum (Euler equation):

$$-\frac{U_{n,t}}{U_{c,t}} = \frac{W_t}{P_t} \quad (\text{A3})$$

$$Q_t = \beta \tilde{E}_t^i \left[ \frac{U_{c,t+1}}{U_{c,t}} \frac{P_t}{P_{t+1}} \right] \quad (\text{A4})$$

where  $\tilde{E}_t^i$  is the forecast made by agent  $i$  in period  $t$  using the behavioral heuristic explained in the main text.

Assume a CES utility function

$$U(C_t^i, N_t^i) = \frac{C_t^{i,1-\sigma}}{1-\sigma} - \frac{N_t^{i,1+\varphi}}{1+\varphi} \quad (\text{A5})$$

First order optimality conditions can then be written as:

$$\frac{w_t}{P_t} = C_t^{i,\sigma} N_t^{i,\varphi} \quad (\text{A6})$$

$$Q_t = \beta \tilde{E}_t^i \left[ \left( \frac{C_{t+1}^i}{C_t^i} \right)^{-\sigma} \frac{P_t}{P_{t+1}} \right] \quad (\text{A7})$$

Log-linearization (A6) yields the labour supply equation

$$w_t - p_t = \sigma c_t^i + \varphi n_t^i \quad (\text{A8})$$

where lower case letters are natural logarithms. We will not use this labour supply equation as I currently assume full wage flexibility.

Similarly log-linearization (A7) yields the consumption equation (Euler equation) for individual i:

$$c_t^i = \tilde{E}_t^i c_{t+1}^i - \frac{1}{\sigma} (r_t - \tilde{E}_t^i \pi_{t+1} - \rho) \quad (\text{A9})$$

where the interest rate  $r_t = -\log(Q_t)$ , the inflation rate  $\pi_t = \log P_{t+1} - \log P_t$  and  $\rho = -\log \beta$ .

We follow Hommes and Lustenhouwer (2016) in assuming that the probability to follow a particular forecasting rule (heuristic) in period t is the same across agents, and independent of the heuristic they followed in the past. This follows from the fact that agents are not inherently different, but that each of them is confronted with the same choice between being following a naïve or fundamentalist forecasting rule. In addition, as in Hommes and Lustenhouwer(2016), we assume “agents know that all agents have the same probability to follow a particular heuristic in the future, and that they know that consumption decisions only differ between households in so far as their expectations are different”. In this case households’ forecasts about their individual consumption must be the same as their forecast of the consumption of any other individual. It follows that the individual’s forecast of his own consumption will coincide with the forecast of aggregate consumption:

$$\tilde{E}_t^i c_{t+1}^i = \tilde{E}_t^i C_{t+1} \quad (\text{A10})$$

where  $C_{t+1}$  is aggregate consumption.

This allows us to rewrite the Euler equation as

$$c_t^i = \tilde{E}_t^i C_{t+1} - \frac{1}{\sigma} (r_t - \tilde{E}_t^i \pi_{t+1} - \rho) \quad (\text{A11})$$

In equilibrium aggregate demand = aggregate supply of output, i.e.  $c_t = y_t$

Assume that agents understand market clearing. As a result, their forecast of consumption coincides with their forecast of output. It can be written as

$$\tilde{E}_t^i c_{t+1} = \tilde{E}_t^i y_{t+1} \quad (\text{A12})$$

As a result, (A11) can be written as

$$c_t^i = \tilde{E}_t^i y_{t+1} - \frac{1}{\sigma} (r_t - \tilde{E}_t^i \pi_{t+1} - \rho) \quad (\text{A13})$$

Aggregating this expression over all agents  $i$ , and using the market clearing condition, yield

$$y_t = \tilde{E}_t y_{t+1} - \frac{1}{\sigma} (r_t - \tilde{E}_t \pi_{t+1} - \rho) \quad (\text{A14})$$

This is the aggregate demand equation used in the main text (without inertia). Thus the aggregate demand equation in our behavioral model can be micro-founded.

The aggregate demand equation used in the main text includes a lagged output gap. Such a lagged output gap can be introduced by assuming habit formation (see Fuhrer(200), Dennis(2008)). We then have a utility function of the form:

$$E_0 \sum_{t=0}^{\infty} \beta^t U(C_t^i, H_t^i, N_t^i) \quad (\text{A15})$$

where  $H_t^i$  is the habit stock of agent  $i$ .

Assuming the habit stock obeys the expression

$$H_t^i = \eta C_{t-1}^i$$

where it is assumed that external habit formation (see Dennis(2008)). This allows us to derive an aggregate demand equation of the form (see Dennis(2008))

$$y_t = \frac{1}{1+\eta} \tilde{E}_t y_{t+1} + \frac{\eta}{1+\eta} y_{t-1} - \frac{1}{\sigma} (r_t - \tilde{E}_t \pi_{t+1} - \rho) \quad (\text{A16})$$

which is the aggregate demand equation (1) used in the main text where

$$a_1 = \frac{1}{1+\eta}$$

## 2. Aggregate supply

There is a continuum of firms each producing a differentiated good  $j$  in monopolistically competitive markets.

The production function of firm  $j$  is specified as follows

$$Y_t^j = A_t N_t^{j,1-\alpha} \quad (\text{A17})$$

We introduce a “New-Keynesian” feature in the model which is that prices are sticky. It is customary to assume so-called Calvo pricing. It is possible to micro-found the behavioral model under the same assumptions about price rigidity as in the standard DSGE-models.

Calvo pricing assumes that each firm will reset prices in period  $t$  with probability  $1 - \theta$ , where  $\theta$  is the fraction of firms that keep their prices fixed. Thus,  $\theta$  can be considered as a measure of prices stickiness.

Each period firms that have drawn the “Calvo lottery ticket”, i.e. are allowed to change their price, will set that price,  $P_t^*$ , such that it maximizes the current value of profits generated while that price remains effective

Firms maximize expected profits with respect to  $P_t^*$

$$\sum_{k=0}^{\infty} (\beta\theta)^k \tilde{E}_t^j \left[ P_t^{j,*} Y_{t+k/t}^j - \Psi_{t+k}(Y_{t+k/t}^j) \right] \quad (\text{A18})$$

subject to the demand constraints

$$Y_{t+k/t}^j = \left( \frac{P_t^*}{P_{t+k}} \right)^{-\varepsilon} C_{t+k}^j \quad (\text{A19})$$

Where  $\Psi_{t+k}(Y_{t+k/t}^j)$  is the cost function,  $Y_{t+k/t}^j$  is the output of the firm that last reset its price in period  $t$ .

The first order condition of an optimum is:

$$\sum_{k=0}^{\infty} (\beta\theta)^k \tilde{E}_t^j \left[ Y_{t+k/t}^j \left( P_t^{j,*} - M\psi_{t+k/t}^j \right) \right] = 0 \quad (\text{A20})$$

where  $\psi_{t+k/t}$  is the marginal cost in  $t+k$  for firm that last reset its price in  $t$  and  $M$  is mark-up, i.e.

$$M = \frac{\varepsilon}{\varepsilon-1} \quad (\text{A21})$$

Log-linearizing and solving for the price, yields

$$p_t^{j,*} = \mu + (1 - \beta\theta) \sum_{k=0}^{\infty} (\beta\theta)^k \tilde{E}_t^j \left[ mc_{t+k/t}^j + p_{t+k}^j \right] \quad (\text{A22})$$

where  $\mu$  is the desired mark-up,  $mc_{t+k/t}$  is the (real) marginal cost. Note that  $mc_{t+k/t} + p_{t+k}$  is the nominal marginal cost.

Equation (A21) says that firms resetting their price will choose a price equal to desired (equilibrium) mark-up plus expected marginal costs that will prevail as long as the price is effective (is not changed).

Using

$$\pi_t = (1 - \theta)(p_t^* - p_{t-1}) \quad (\text{A23})$$

We obtain

$$\pi_t^j = \lambda \sum_{k=0}^{\infty} \beta^k \tilde{E}_t^j [\widehat{mc}_{t+k}^j] \quad (\text{A24})$$

where  $b_2 = \frac{(1-\theta)(1-\beta\theta)}{\theta} \frac{1-\alpha}{1-\alpha\varepsilon}$  and  $\widehat{mc}_{t+k}^j$  is the marginal cost expressed as a deviation from the steady state.

Thus when the deviation of marginal cost from steady state is positive a fraction of prices is adjusted upwards, leading to more inflation.

Just as in the case of the demand equation the discrete choice model of the selection of forecasting rules implies that

$$\tilde{E}_t^j [\widehat{mc}_{t+k}^j] = \tilde{E}_t^j [\widehat{mc}_{t+k}] \quad (\text{A25})$$

Finally we can rewrite

$$\pi_t^j = \beta \tilde{E}_t^j [\pi_{t+1}] + \lambda \widehat{mc}_t \quad (\text{A26})$$

Aggregating over all firms  $j$  (see Hommes and Lustenhouwer(2016), we obtain

$$\pi_t = \beta \widetilde{E}_t [\pi_{t+1} + \lambda mc_t] \quad (\text{A27})$$

The last step consists in relating marginal cost to the output gap

$$\pi_t = \beta \widetilde{E}_t [\pi_{t+1}] - \lambda \hat{\mu}_t \quad (\text{A28})$$

where  $\hat{\mu}_t = \mu_t - \mu = -\widehat{mc}_t$  and  $\lambda = \frac{(1-\theta)(1-\beta\theta)}{\theta} \frac{1-\alpha}{1-\alpha+\alpha\varepsilon}$

In a way analogous to the assumptions on the price-setting constraints facing firms, assume that for each period only a fraction  $1 - \theta_w$  of households drawn randomly from the population reoptimize their posted nominal wage. We now consider how households choose the wage for their labour when allowed to reoptimize that wage. The household will choose  $w_t$  at period  $t$  in order to maximize.

$$\tilde{E}_t^i \left\{ \sum_{k=0}^{\infty} (\beta \theta_w)^k U(C_{t+k|t}^i, N_{t+k|t}^i) \right\} \quad (\text{A29})$$

Where  $C_{t+k|t}^i$  and  $N_{t+k|t}^i$  respectively denote the consumption and labour supply in period  $t+k$  of a household  $I$  that last rest its wage in period  $t$ . Note that the utility generated under any

other wage set in the future is irrelevant from the point of view of the optimal setting of the current wage, and thus can be ignored in (A28).

Given the utility function specified in (A5), the first-order condition associated with the problem above is given by

$$\sum_{k=0}^{\infty} (\beta \theta_w)^k \tilde{E}_t^i \left\{ N_{t+k|t} U_c(C_{t+k|t}^i, N_{t+k|t}^i) \left( \frac{w_t}{p_{t+k}} - M_w \text{MRS}_{t+k|t} \right) \right\} = 0 \quad (\text{A30})$$

$\text{MRS}_{t+k|t}^i = -\frac{U_n(C_{t+k|t}^i, N_{t+k|t}^i)}{U_c(C_{t+k|t}^i, N_{t+k|t}^i)}$  denote the marginal rate of substitution between consumption and labour in period  $t+k$  for the household resetting the wage in period  $t$  and  $M_w = \frac{\varepsilon_w}{1-\varepsilon_w}$ . Note that  $\varepsilon_w$  measures the elasticity of substitution among labour varieties.

Log-linearizing (A30) around the steady state (zero inflation) yields the following approximate wage setting rule

$$w_t^* = \mu^w + (1 - \beta \theta_w) \sum_{k=0}^{\infty} (\beta \theta_w)^k \tilde{E}_t^i \{ mrs_{t+k|t} + p_{t+k} \} \quad (\text{A31})$$

Where  $\mu^w$  is household markup.  $mrs_{t+k|t}$  is the (log) marginal rate of substitution in period  $t+k$  for a household that reset its wage in period  $t$ .

Using  $\pi_t^w = (1 - \theta_w)(w_t - w_{t-1})$

We obtain:

$$\pi_t^w = \beta \tilde{E}_t^i \{ \pi_{t+1}^w \} - \lambda_w \hat{\mu}_t^w \quad (\text{A32})$$

Where  $\lambda_w = \frac{(1-\theta_w)(1-\beta\theta_w)}{\theta_w(1+\varepsilon_w\varphi)}$  and  $\hat{\mu}_t^w = \mu_t^w - \mu^w$

Just as in the demand equation and price setting equations, the discrete choice model of the selection of forecasting rules (concerning wages inflation) implies that it is feasible to aggregate over all households  $i$ , hence:

$$\pi_t^w = \beta \tilde{E}_t \{ \pi_{t+1}^w \} - \lambda_w \hat{\mu}_t^w \quad (\text{A33})$$

To obtain the Philips curve used in our model, we follow Galí (2008):

Define real wage  $\omega_t = w_t - p_t$ , real natural wage  $\omega_t^n = w_t^n - p_t^n$ , and real wage gap  $\tilde{\omega}_t = \omega_t - \omega_t^n$ ,

$$\hat{\mu}_t^w = \tilde{\omega}_t - \left( \sigma + \frac{\varphi}{1-\alpha} \right) y_t$$

$$\hat{\mu}_t = -\tilde{\omega}_t - \frac{\alpha}{1-\alpha} y_t$$

Referring to Equation (A26), the New Keynesian Philips curve is

$$\begin{aligned} \pi_t &= \beta \tilde{E}_t[\pi_{t+1}] - \lambda \hat{\mu}_t \\ &= \beta \tilde{E}_t[\pi_{t+1}] + \lambda(\tilde{\omega}_t + \frac{\alpha}{1-\alpha} y_t) \\ &= \beta \tilde{E}_t[\pi_{t+1}] + \lambda(\hat{\mu}_t^w + (\sigma + \frac{\varphi}{1-\alpha})y_t + \frac{\alpha}{1-\alpha} y_t) \\ &= \beta \tilde{E}_t[\pi_{t+1}] + \lambda \left( \frac{\sigma(1-\alpha) + \varphi + \alpha}{1-\alpha} \right) y_t + \lambda \hat{\mu}_t^w \\ &= \beta \tilde{E}_t[\pi_{t+1}] + b_2 y_t + \lambda \hat{\mu}_t^w \end{aligned}$$

where  $b_2 = \frac{(1-\theta)(1-\beta\theta)}{\theta} \frac{\sigma(1-\alpha) + \varphi + \alpha}{1-\alpha + \alpha\epsilon}$

To obtain an aggregate supply equation with a lagged inflation, as we have in the main text an indexation scheme has to be introduced. In such an indexation scheme the prices that in the context of the Calvo rule cannot be optimized in period t are indexed to inflation in period t-1. This is done in Smets and Wouters(2003). It is shown there that with indexation the aggregate supply curve is of the form:

$$\pi_t = \frac{\beta}{1 + \beta \Lambda} \tilde{E}_t[\pi_{t+1}] + \frac{\xi}{1 + \beta \Lambda} \pi_{t-1} + b_2 y_t + \lambda \hat{\mu}_t^w$$

where  $\Lambda$  expresses the degree of indexation. When  $\Lambda = 0$  there is no indexation and we obtain an aggregate supply curve without lagged inflation. When  $\Lambda = 1$  there is full indexation and we obtain the aggregate supply curve used in the main text. In that case the coefficients on the forward looking and lagged inflation add up to 1. This leads to equation (2) in the main text.

## APPENDIX 2: Selecting the forecasting rules in output forecasting

We define the forecast performance (utility) of a using particular rule as follows<sup>5</sup>.

$$U_{f,t} = -\sum_{k=0}^{\infty} \omega_k [y_{t-k-1} - \tilde{E}_{f,t-k-2} y_{t-k-1}]^2 \quad (B1)$$

$$U_{e,t} = -\sum_{k=0}^{\infty} \omega_k [y_{t-k-1} - \tilde{E}_{e,t-k-2} y_{t-k-1}]^2 \quad (B2)$$

where  $U_{f,t}$  and  $U_{e,t}$  are the utilities of the fundamentalist and naïve rules, respectively. These are defined as the negative of the mean squared forecasting errors (MSFEs) of the forecasting rules;  $\omega_k$  are geometrically declining weights. We make these weights declining because we assume that agents tend to forget. Put differently, they give a lower weight to errors made far in the past as compared to errors made recently. The degree of forgetting turns out to play a major role in our model. This was analyzed in De Grauwe(2012).

Agents evaluate these utilities in each period. We apply discrete choice theory (see Anderson, de Palma, and Thisse, (1992) and Brock & Hommes(1997)) in specifying the procedure agents follow in this evaluation process. If agents were purely rational they would just compare  $U_{f,t}$  and  $U_{e,t}$  in (10) and (11) and choose the rule that produces the highest value. Thus under pure rationality, agents would choose the fundamentalist rule if  $U_{f,t} > U_{e,t}$ , and vice versa. However, psychologists have stressed that when we have to choose among alternatives we are also influenced by our state of mind (see Kahneman(2002)). The latter can be influenced by many unpredictable things. One way to formalize this is that the utilities of the two alternatives have a deterministic component (these are  $U_{f,t}$  and  $U_{e,t}$ ) and a random component  $\xi_{f,t}$  and  $\xi_{e,t}$ . The probability of choosing the fundamentalist rule is then given by

$$\alpha_{f,t} = P \left[ (U_{f,t} + \xi_{f,t}) > (U_{e,t} + \xi_{e,t}) \right] \quad (B3)$$

In words, this means that the probability of selecting the fundamentalist rule is equal to the probability that the stochastic utility associated with using the fundamentalist rule exceeds the

---

<sup>5</sup> (B1) and (B2) can be derived from the following equation:

$$U_t = \rho U_{t-1} + (1 - \rho) [y_{t-1} - \tilde{E}_{t-2} y_{t-1}]^2 \quad (B1')$$

where  $\rho$  can be interpreted as a memory parameter. When  $\rho = 0$  only the last period's forecast error is remembered; when  $\rho = 1$  all past periods get the same weight and agents have infinite memory.

We will generally assume that  $0 < \rho < 1$ . Using (9') we can write

$$U_{t-1} = \rho U_{t-2} + (1 - \rho) [y_{t-2} - \tilde{E}_{t-3} y_{t-2}]^2 \quad (B1'')$$

Substituting (B1'') into (B1') and repeating such substitutions ad infinitum yields the expression (B1) where

$$\omega_k = (1 - \rho) \rho^k$$

stochastic utility of using the naïve rule. In order to derive a more precise expression one has to specify the distribution of the random variables  $\xi_{f,t}$  and  $\xi_{e,t}$ . It is customary in the discrete choice literature to assume that these random variables are logistically distributed. One then can obtain the probabilities specified in (8) and (9).

The parameter  $\gamma$  measures the “intensity of choice”. It is related to the variance of the random components. Defining  $\xi_t = \xi_{f,t} - \xi_{e,t}$ , we can write (see Anderson, Palma and Thisse(1992)):

$$\gamma = \frac{1}{\sqrt{\text{var}(\xi_t)}}$$

When  $\text{var}(\xi_t)$  goes to infinity,  $\gamma$  approaches 0. In that case agents’ utility is completely overwhelmed by random events making it impossible for them to choose rationally between the two rules. As a result, they decide to be fundamentalist or extrapolator by tossing a coin and the probability to be fundamentalist (or extrapolator) is exactly 0.5. When  $\gamma = \infty$  the variance of the random components is zero (utility is then fully deterministic) and the probability of using a fundamentalist rule is either 1 or 0.

### **Appendix 3: The predictive power of initial conditions: econometric analysis**

In this appendix, using the impulse responses data from our theoretical model, we analyze econometrically what the power is of initial conditions to predict in which cluster the output gap will be pushed 12 periods after the supply shock and 4 periods after the demand shock. As before we distinguish between a large and a small shock.

We have observed that after a large shock the output gap appears to be following two separate distributions. Standard models will generally not be helpful when one has data from more than one distribution with no information to identify which observation goes with which distribution,. However, Finite Mixture Models (FMM) might come to the rescue (McLachlan and Peel, 2000)). They use a mixture of parametric distributions to model data, estimating both the parameters for the separate distributions and the probabilities of component membership for each observation.

To formally test these ideas, we collect the simulation data under different supply and demand shocks assuming either small (=1 std) or large (=10 std) shocks. In each specific shock, we fit these data with finite mixture models. As discussed earlier, the data generated from our theoretical model suggest that the output gap may be from more than one distribution. We fit the data using the finite model with two classes (assuming two distributions) and then a similar model with only one class (assuming one distribution).

Both the Akaike information criterion (AIC) and the Bayesian information criterion (BIC) from the two models favour the two-class model. This confirms that our theoretical model in fact generate output gaps with more than one distribution. We proceed with the two-class model in analyzing how expectations and other initial conditions are associated with the future output gap. The estimates results are shown in Tables 1 and 2.

In Table 1, we find that in the case of a large demand shock the output gap expectation is a perfect predictor of the future output. The coefficient is -105.1448 indicating that as long as the output gap expectation is positive, the probability of falling in a bad cluster (mean value at -0.4693) is almost at zero. Similarly, in the case of a large supply shock inflation expectation perfectly predicts the future output gap. The coefficient of 153.9678 informs us that when the inflation expectation is positive, the probability of being in a bad cluster (mean at -1.0819) is close to 1. By contract, when shocks are small, expectations are much less powerful in predicting the future clustering of the output gap. We observe from table 1 that output

expectations in the case of a small demand shock is a significant factor associated with the probabilities of the clusters. In a small supply shock, we do not find any significant factors that can be associated with the probabilities of the clusters.

Table 2 presents the predictive power of the initial conditions conditional on being in the good, respectively the bad cluster. We find significance of the initial output and initial forecasts of output in the case of a large and a small demand shock. Similarly, we find significance of initial inflation and inflation forecasts in the case of both a large and small supply shock. Thus, initial conditions continue to matter once the economy is traveling along one of these two trajectories.
